Multivariate Analysis

Introduction

The body of statistical methodology used to analyze simultaneous measurements on many variables is called *multivariate analysis*. Many multivariate methods are based on an underlying probability model known as the *multivariate normal* (see **Normal Distribution**). Other methods are *ad hoc* in nature and are justified by logical or common-sense arguments. Regardless of their origin, multivariate techniques invariably must be implemented on a computer. Current sophisticated statistical software packages make the implementation step easier.

Multivariate analysis is a “mixed bag”. It is difficult to establish a classification scheme for multivariate techniques that is both widely accepted and also indicates the appropriateness of the techniques. One classification distinguishes techniques designed to study interdependent relationships from those designed to study dependent relationships. Another classifies techniques according to the number of populations and the number of sets of variables being studied. Yet another classification may distinguish those methods applicable to metric data from those applicable to nonmetric data. This chapter is divided into sections according to inferences about means, inferences about **covariance** structure, and techniques for classification or grouping. This should not, however, be regarded as an attempt to place each method into a slot. Rather, the choice of methods and the types of analyses employed are determined largely by the objectives of the investigation.

The objectives of scientific investigations, for which multivariate methods most naturally lend themselves, include the following:

1. data reduction or structural simplification,
2. sorting and grouping,
3. investigation of the dependence among variables,
4. forecasting and prediction, and
5. hypothesis construction and testing.

A Historical Perspective

Many current multivariate statistical procedures were developed during the first half of the twentieth century. A reasonably complete list of the developers

would be voluminous. However, a few individuals can be cited as making important initial contributions to the theory and practice of multivariate analysis. Francis Galton and Karl Pearson did pioneering work in the areas of *correlation* (see **Correlation**) and regression analysis. R. A. Fisher’s derivation of the exact distribution of the sample correlation coefficient and related quantities provided the impetus for the multivariate distribution theory. C. Spearman and K. Pearson were among the first to work in the area of factor analysis. Significant contributions to multivariate analysis were made during the 1930s by S. S. Wilks (general procedures for testing certain multivariate hypotheses), H. Hotelling (see **Hotelling’s T^2**), principal component analysis, canonical correlation analysis, R. A. Fisher (discrimination and classification), and P. C. Mahalanobis (generalized distance, **hypothesis testing**). J. Wishart derived an important joint distribution of sample variances and covariances that bears his name. Later, M. S. Bartlett and G. E. P. Box contributed to the large-sample theory associated with certain multivariate test statistics.

Many multivariate methods evolved in concert with the development of electronic computers. Specifically, ingenious graphical methods for displaying multivariate data (e.g., Chernoff faces, Andrews plots) can only be conveniently implemented on a computer. Multidimensional scaling and many clustering procedures were not feasible before the advent of fast computers. Several people have exploited the power of the computer to develop procedures for extracting information from very large data sets, and to create informative lower-dimensional representations of multivariate data (see, for example [1], and the references therein).

Notation

The description of multivariate data and the computations required for their analysis are greatly facilitated by the use of matrix algebra. Consequently, the subsequent discussion will rely heavily on the following notation:

$\mathbf{X}$, a $p \times 1$ random vector,

$\mathbf{x}_j$, a $p \times 1$ multivariate observation on $\mathbf{X}$

2 Multivariate Analysis

$$\mathbf{X} = \begin{bmatrix} x_{11} & x_{12} & \cdots & x_{1p} \\ x_{21} & x_{22} & \cdots & x_{2p} \\ \vdots & \vdots & \cdots & \vdots \\ x_{n1} & x_{n2} & \cdots & x_{np} \end{bmatrix}$$

$$= [\mathbf{x}_1, \mathbf{x}_2, \dots, \mathbf{x}_p] \quad (1)$$

an $n \times p$ matrix. (Each column of $\mathbf{X}$ represents a multivariate observation.)

$$\bar{\mathbf{x}} = [\bar{x}_1, \bar{x}_2, \dots, \bar{x}_p]'$$

$$= \left\{ \bar{x}_i = \frac{1}{n} \sum_{j=1}^n x_{ij}; i = 1, 2, \dots, p \right\} \quad (2)$$

a $p \times 1$ vector of sample means

$$\mathbf{S} = \left\{ s_{ik} = \frac{1}{n-1} \sum_{j=1}^n (x_{ij} - \bar{x}_i)(x_{kj} - \bar{x}_k); \right.$$

$$i, k = 1, 2, \dots, p \left. \right\} \quad (3)$$

a $p \times p$ symmetric matrix of sample variances and covariances.

$$\mathbf{R} = \left\{ r_{ik} = \frac{s_{ik}}{\sqrt{s_{ii}}\sqrt{s_{kk}}} \right\} \quad (4)$$

a $p \times p$ symmetric matrix of sample correlation coefficients

$$\boldsymbol{\mu} = \{\mu_i\} = E(\mathbf{X}) \quad (5)$$

a $p \times 1$ vector of population means. ($E(\cdot)$ is the expectation (see **Expectation**) operator.)

$$\boldsymbol{\Sigma} = \{\sigma_{ij}\} = E(\mathbf{X} - \boldsymbol{\mu})(\mathbf{X} - \boldsymbol{\mu})' \quad (6)$$

a $p \times p$ symmetric matrix of population variances and covariances.

$$\boldsymbol{\rho} = \left\{ \rho_{ij} = \frac{\sigma_{ij}}{\sqrt{\sigma_{ii}}\sqrt{\sigma_{jj}}} \right\} \quad (7)$$

a $p \times p$ symmetric matrix of population correlation coefficients.

$$\mathbf{Z} = \left\{ Z_i = \frac{X_i - \mu_i}{\sqrt{\sigma_{ii}}} \right\} \quad (8)$$

a $p \times 1$ vector of standardized variables.

Multivariate Normal Distribution

A generalization of the familiar bell-shaped normal density to several dimensions plays a fundamental role in multivariate analysis. In fact, many multivariate techniques assume that the data were generated from a *multivariate* normal distribution. Although real data are never *exactly* multivariate normal, the normal density is often a useful approximation to the “true” population distribution. Therefore, the *normal distribution* (see **Normal Distribution**) serves as a *bona fide* population model in some instances. Also, the sampling distributions of many multivariate statistics are approximately normal, regardless of the form of the parent population, because of a *central limit effect*.

The p -dimensional normal density for the random vector $\mathbf{X} = [X_1, X_2, \dots, X_p]'$, evaluated at the point $\mathbf{x} = [x_1, x_2, \dots, x_p]'$, is given by

$$f(\mathbf{x}) = (2\pi)^{-p/2} |\boldsymbol{\Sigma}|^{-1/2}$$

$$\times \exp \left\{ -\frac{1}{2} (\mathbf{x} - \boldsymbol{\mu})' \boldsymbol{\Sigma}^{-1} (\mathbf{x} - \boldsymbol{\mu}) \right\} \quad (9)$$

where $-\infty < x_i < \infty, i = 1, 2, \dots, p$. Here $\boldsymbol{\mu}$ is the population mean vector, $\boldsymbol{\Sigma}$ is the population's variance-covariance matrix, $|\boldsymbol{\Sigma}|$ is the determinant of $\boldsymbol{\Sigma}$, and $\exp(\cdot)$ stands for the exponential function. We denote this p -dimensional normal density by $N_p(\boldsymbol{\mu}, \boldsymbol{\Sigma})$.

Contours of constant density for the p -dimensional normal distribution are ellipsoids defined by $\mathbf{x}$ such that

$$(\mathbf{x} - \boldsymbol{\mu})' \boldsymbol{\Sigma}^{-1} (\mathbf{x} - \boldsymbol{\mu}) = c^2 \quad (10)$$

These ellipsoids are centered at $\boldsymbol{\mu}$ and have axes $\pm c\sqrt{\lambda_i} \mathbf{e}_i$, where $\boldsymbol{\Sigma} \mathbf{e}_i = \lambda_i \mathbf{e}_i, i = 1, 2, \dots, p$. That is, $\lambda_i, \mathbf{e}_i$ are the eigenvalue (normalized) eigenvector pairs associated with $\boldsymbol{\Sigma}$.

The following are true for a random vector $\mathbf{X}$ having a multivariate normal distribution.

1. Linear combinations of the components of $\mathbf{X}$ are normally distributed.
2. All subsets of the components of $\mathbf{X}$ have a (multivariate) normal distribution.
3. Zero covariance implies that the corresponding components are distributed independently.
4. The conditional distributions of the multivariate components are (multivariate) normal.

(See references [2, Chapter 2] and [3, Section 8a] for more discussion of the multivariate normal distribution.) Because these properties make the normal distribution easy to manipulate, it has been overemphasized as a population model.

To some degree, the *quality* of inferences made by some multivariate methods depend on how closely the true parent population resembles the multivariate normal form. It is imperative, then, that procedures exist for detecting cases in which the data exhibit moderate to extreme departures from what is expected under multivariate normality.

Sometimes nonnormal data can be made to look more normal by considering transformations (*see Box and Cox Transformation*) of the data. Normal theory analyses can then be carried out with the suitably transformed data [4, Section 4.8; 5, Section 4.2]. Latest advances in the theory of *discrete* multivariate analysis are contained in reference [6].

Sampling Distributions of $\bar{\mathbf{X}}$ and $\mathbf{S}$

The tentative assumption that the columns of the data matrix, treated as random vectors, constitute a random sample from a normal population, with mean $\boldsymbol{\mu}$ and covariance $\boldsymbol{\Sigma}$, completely determines the sampling distribution of $\bar{\mathbf{X}}$ and $\mathbf{S}$. We now summarize the sampling distribution results.

Let $\mathbf{X}_1, \mathbf{X}_2, \dots, \mathbf{X}_n$ be a random sample of size n from a p -variate *normal* distribution with mean $\boldsymbol{\mu}$ and covariance matrix $\boldsymbol{\Sigma}$. Then (see [2, Sections 3.3 and 7.2; 3, Section 8b]):

1. $\bar{\mathbf{X}}$ is distributed as $N_p(\boldsymbol{\mu}, (1/n)\boldsymbol{\Sigma})$.
2. $(n-1)\mathbf{S}$ is distributed as a Wishart random matrix with $n-1$ **degrees of freedom** (df).
3. $\bar{\mathbf{X}}$ and $\mathbf{S}$ are independent.

Because $\boldsymbol{\Sigma}$ is unknown, the distribution of $\bar{\mathbf{X}}$ cannot be used directly to make inferences about $\boldsymbol{\mu}$. However, $\mathbf{S}$ provides independent information about $\boldsymbol{\Sigma}$ and the distribution of $\mathbf{S}$ does not depend on $\boldsymbol{\mu}$. This allows one to construct a statistic for making inferences about $\boldsymbol{\mu}$.

Selected Problems about Means

Single-Population Mean Vector

An immediate objective in many multivariate studies is to make statistical inferences about population

mean vectors. As an initial example, consider the problem of testing whether a multivariate normal population mean vector has a particular value $\boldsymbol{\mu}_0$.

Let the null and alternative hypotheses be $H_0 : \boldsymbol{\mu} = \boldsymbol{\mu}_0$ and $H_1 : \boldsymbol{\mu} \neq \boldsymbol{\mu}_0$, respectively. Once the sample is in hand, a sample mean vector far from $\boldsymbol{\mu}_0$ tends to discredit H_0 . A test of H_0 based on the (statistical) distance of $\bar{\mathbf{x}}$ from $\boldsymbol{\mu}_0$ (assuming the population covariance matrix $\boldsymbol{\Sigma}$ is unknown) can be carried out using Hotelling's T^2 ,

$$T^2 = n(\bar{\mathbf{x}} - \boldsymbol{\mu}_0)' \mathbf{S}^{-1} (\bar{\mathbf{x}} - \boldsymbol{\mu}_0) \quad (11)$$

Hotelling's T^2 is a distance measure that takes account of the joint variability of the p measured variables. Under H_0 , T^2 is distributed as

$$[(n-1)p/(n-p)]F_{p, n-p} \quad (12)$$

where n is the **sample size** and $F_{p, n-p}$ denotes an F random variable with p and $n-p$ df. Let $F_{p, n-p}(\alpha)$ be the upper 100α th percentage point of this F distribution (*see Probability Density Functions*). The hypothesis $H_0 : \boldsymbol{\mu} = \boldsymbol{\mu}_0$ is rejected at the α level of significance if

$$T^2 > [(n-1)p/(n-p)]F_{p, n-p}(\alpha) \quad (13)$$

Example 1 The quality-control department of a microwave oven manufacturer is concerned about the radiation emitted by the ovens. They record radiation measurements with the oven doors opened and closed. Measurements for a random sample of microwave ovens could then be compared with the standards for radiation emission set by the manufacturer.

Other principles of test construction (e.g., likelihood ratio, union–intersection principle) also lead to the use of Hotelling's T^2 in this testing situation.

Hotelling's T^2 statistic has numerous other applications. There are multivariate analogs of the paired and two-sample univariate t statistics. For applications, see references [4, Chapter 5; 7, Chapter 2; 8, Chapter 5].

Several-Population Means, Multivariate Analysis of Variance* (MANOVA)

Multivariate analysis of variance (MANOVA) is concerned with inferences about several population means. It is a direct generalization of the *analysis*

4 Multivariate Analysis

of variance (ANOVA) (see **Analysis of Variance**) to the case of more than one response variable. In its simplest form, one-way MANOVA, random samples are collected from each of g populations and arranged as

$$\begin{array}{llll} \text{Population 1} & \mathbf{X}_{11}, \mathbf{X}_{12}, & \dots, & \mathbf{X}_{1n_1} \\ \text{Population 2} & \mathbf{X}_{21}, \mathbf{X}_{22}, & \dots, & \mathbf{X}_{2n_2} \\ \vdots & \vdots & & \vdots \\ \text{Population } g & \mathbf{X}_{g1}, \mathbf{X}_{g2}, & \dots, & \mathbf{X}_{gn_g} \end{array}$$

MANOVA is used first to investigate whether the population mean vectors are the same, and if not, which mean components differ significantly. It is assumed that

1. $\mathbf{X}_{l1}, \mathbf{X}_{l2}, \dots, \mathbf{X}_{ln_l}$ is a random sample of size n_l from a population with mean $\boldsymbol{\mu}_l$, $l = 1, 2, \dots, g$. The random samples from different populations are independent.
2. All populations have a common covariance matrix $\boldsymbol{\Sigma}$.
3. Each population is multivariate normal.

Condition 3 can be relaxed by applying the central limit theorem when the sample sizes n_l are large. The model states that the mean $\boldsymbol{\mu}_l$ consists of a common part $\boldsymbol{\mu}$ plus an amount $\boldsymbol{\tau}_l$ due to the l th treatment. According to the model, *each component* of the observation vector $\mathbf{X}_{lj}$ satisfies the univariate

model. The errors for the components of $\mathbf{X}_{lj}$ are correlated, but the covariance matrix $\boldsymbol{\Sigma}$ is the same for all populations (see Table 1).

A vector of observations may be decomposed as suggested by the model. Thus,

$$\begin{aligned} \mathbf{x}_{lj} &= \bar{\mathbf{x}} + (\bar{\mathbf{x}}_l - \bar{\mathbf{x}}) + (\mathbf{x}_{lj} - \bar{\mathbf{x}}_l) \\ (\text{observation}) &= \begin{bmatrix} \text{overall} \\ \text{sample} \\ \text{mean } \hat{\boldsymbol{\mu}} \end{bmatrix} + \begin{bmatrix} \text{estimated} \\ \text{treatment} \\ \text{effect } \hat{\boldsymbol{\tau}}_l \end{bmatrix} \\ &\quad + \begin{pmatrix} \text{residual} \\ \hat{\mathbf{e}}_{lj} \end{pmatrix} \end{aligned} \quad (14)$$

which leads to a decomposition of the **sum of squares** and cross-products matrix

$$\sum_{l=1}^g \sum_{j=1}^{n_l} (\mathbf{x}_{lj} - \bar{\mathbf{x}})(\mathbf{x}_{lj} - \bar{\mathbf{x}})' \quad (15)$$

and the MANOVA table (see Table 2). One test of $H_0: \boldsymbol{\tau}_1 = \boldsymbol{\tau}_2 = \dots = \boldsymbol{\tau}_g = \mathbf{0}$ involves *generalized variances*. We reject H_0 if the ratio of generalized variances

$$\begin{aligned} \Lambda &= \frac{|\mathbf{W}|}{|\mathbf{B} + \mathbf{W}|} \\ &= \left| \frac{\sum_{l=1}^g \sum_{j=1}^{n_l} (\mathbf{x}_{lj} - \bar{\mathbf{x}}_l)(\mathbf{x}_{lj} - \bar{\mathbf{x}}_l)'}{\sum_{l=1}^g \sum_{j=1}^{n_l} (\mathbf{x}_{lj} - \bar{\mathbf{x}})(\mathbf{x}_{lj} - \bar{\mathbf{x}})'} \right| \end{aligned} \quad (16)$$

Table 1 MANOVA model for comparing g population mean vectors

$\mathbf{X}_{lj} = \boldsymbol{\mu} + \boldsymbol{\tau}_l + \mathbf{e}_{lj}$, $j = 1, 2, \dots, n_l$, and $l = 1, 2, \dots, g$, where $\mathbf{e}_{lj}$ are independent $N_p(\mathbf{0}, \boldsymbol{\Sigma})$ variables. Here the parameter vector $\boldsymbol{\mu}$ is an overall mean (level) and $\boldsymbol{\tau}_l$ represents the l th treatment effect with, for instance,

$$\sum_{l=1}^g n_l \boldsymbol{\tau}_l = \mathbf{0}$$

Table 2 MANOVA table for comparing population mean vectors

Source of variation	Matrix of (SSP) ^(a)	Degrees of freedom (df)
Treatment	$\mathbf{B} = \sum_{l=1}^g n_l (\bar{\mathbf{x}}_l - \bar{\mathbf{x}})(\bar{\mathbf{x}}_l - \bar{\mathbf{x}})'$	$g - 1$
Residual (error)	$\mathbf{W} = \sum_{l=1}^g \sum_{j=1}^{n_l} (\mathbf{x}_{lj} - \bar{\mathbf{x}}_l)(\mathbf{x}_{lj} - \bar{\mathbf{x}}_l)'$	$\left(\sum_{l=1}^g n_l \right) - g$
Total (corrected for the mean)	$\mathbf{B} + \mathbf{W} = \sum_{l=1}^g \sum_{j=1}^{n_l} (\mathbf{x}_{lj} - \bar{\mathbf{x}})(\mathbf{x}_{lj} - \bar{\mathbf{x}})'$	$\left(\sum_{l=1}^g n_l \right) - 1$

^(a) SSP: sum of square and cross product

is too small. The quantity $\Lambda = |\mathbf{W}|/|\mathbf{B} + \mathbf{W}|$ is called *Wilks' lambda* after its proposer S. Wilks.

A comparison of the MANOVA table with the familiar $p = 1$ ANOVA table reveals that they are of the same structure. For the multivariate generalization, squares $(\bar{x}_i - \bar{x})^2$ are replaced by sums-of-squares and cross-products matrices $(\bar{\mathbf{x}}_i - \bar{\mathbf{x}})(\bar{\mathbf{x}}_i - \bar{\mathbf{x}})'$. The same type of replacement holds for any fixed ANOVA, so MANOVA tables can be constructed easily for any of the common designs (see, for example, references [2, Chapter 8; 4, Chapter 6 and 9; 9, Chapter 11]).

Summary Remarks

Multivariate analysis takes into account the joint variation of several responses. One noticeable difference from the univariate situation is that rejection of a null hypothesis $H_0 : \boldsymbol{\mu} = \boldsymbol{\mu}_0$ must be followed by a determination of which component(s) led to the rejection. Technically, it is at least one linear combination $a_1\mu_1 + \dots + a_p\mu_p = \mathbf{a}'\boldsymbol{\mu}$ that is different from $\mathbf{a}'\boldsymbol{\mu}_0$, but this class typically includes some individual μ_i . As we proceed to several treatments, rejection of the null hypothesis $H_0 : \boldsymbol{\mu}_1 = \boldsymbol{\mu}_2 = \dots = \boldsymbol{\mu}_g$ must be followed by a comparison of the $\boldsymbol{\mu}_i$ to determine which treatments are different and then to determine which components contribute to the difference.

Multivariate Multiple Regression

Regression analysis is the statistical methodology for predicting values of one or more *response* (dependent) variables from a collection of *predictor* (independent) variable values. It can also be used for assessing the effects of the predictor variables on the responses. In its simplest form, it applies to the fitting of a straight line to data.

The classical linear regression model states that the response Y is composed of a mean, which depends in a linear fashion on the predictor variables z_i and random error ϵ which accounts for measurement error and the effects of other variables not explicitly considered in the model (see **Mean Square Error**). The values of the predictor variables recorded from the experiment or set by the investigator are treated as *fixed*. The error (and hence the response) is viewed as a random variable, the behavior of which is characterized by a set of distributional assumptions.

Specifically, the linear regression model with a single response and n measurements on Y and the associated predictors $z_1, z_2, \dots, z_r$ can be written in matrix notation as

$$\mathbf{Y} = \mathbf{Z}\boldsymbol{\beta} + \boldsymbol{\epsilon} \quad (17)$$

with $E(\boldsymbol{\epsilon}) = \mathbf{0}$ and $\text{Cov}(\boldsymbol{\epsilon}) = \sigma^2\mathbf{I}$.

The *least-squares* (see **Least-Squares Estimation**) estimator of $\boldsymbol{\beta}$ is given by $\hat{\boldsymbol{\beta}} = (\mathbf{Z}'\mathbf{Z})^{-1}\mathbf{Z}'\mathbf{Y}$ and σ^2 is estimated by $(\mathbf{Y} - \mathbf{Z}\hat{\boldsymbol{\beta}})'(\mathbf{Y} - \mathbf{Z}\hat{\boldsymbol{\beta}})/(n - r - 1)$. The literature on multiple linear regression is vast; see the numerous books on the subject including references [10, 11].

Multivariate multiple regression is the extension of multiple regression to several response variables. Each response is assumed to follow its own regression model but with the same predictors, so that

$$\begin{aligned} Y_1 &= \beta_{01} + \beta_{11}z_1 + \dots + \beta_{r1}z_r + \epsilon_1 \\ Y_2 &= \beta_{02} + \beta_{12}z_1 + \dots + \beta_{r2}z_r + \epsilon_2 \\ &\vdots \\ Y_m &= \beta_{0m} + \beta_{1m}z_1 + \dots + \beta_{rm}z_r + \epsilon_m \end{aligned} \quad (18)$$

The error term $\boldsymbol{\epsilon} = [\epsilon_1, \epsilon_2, \dots, \epsilon_m]'$ has $E(\boldsymbol{\epsilon}) = \mathbf{0}$ and $\text{Var}(\boldsymbol{\epsilon}) = \boldsymbol{\Sigma}$. Thus, the error terms associated with different responses may be correlated.

To establish notation conforming to the classical linear regression model, let $[z_{j0}, z_{j1}, \dots, z_{jr}]$ denote the values of the predictor variables for the j th trial, $\mathbf{Y}_j = [Y_{j1}, Y_{j2}, \dots, Y_{jm}]'$ the responses, and $\boldsymbol{\epsilon}_j = [\epsilon_{j1}, \epsilon_{j2}, \dots, \epsilon_{jm}]'$ the errors. In matrix notation, the design matrix

$$\mathbf{Z}_{(n \times (r+1))} = \begin{bmatrix} z_{10} & z_{11} & \dots & z_{1r} \\ z_{20} & z_{21} & \dots & z_{2r} \\ \vdots & \vdots & \ddots & \vdots \\ z_{n0} & z_{n1} & \dots & z_{nr} \end{bmatrix} \quad (19)$$

is the same as that for the single-response regression model. The other matrix quantities have multivariate counterparts. Set

$$\mathbf{Y}_{(n \times m)} = \begin{bmatrix} Y_{11} & Y_{12} & \dots & Y_{1m} \\ Y_{21} & Y_{22} & \dots & Y_{2m} \\ \vdots & \vdots & \ddots & \vdots \\ Y_{n1} & Y_{n2} & \dots & Y_{nm} \end{bmatrix} \quad (20)$$

$$\begin{aligned} &= [\mathbf{Y}_{(1)} \quad \mathbf{Y}_{(2)} \quad \dots \quad \mathbf{Y}_{(m)}] \\ \boldsymbol{\beta}_{((r+1) \times m)} &= \begin{bmatrix} \beta_{01} & \beta_{02} & \dots & \beta_{0m} \\ \beta_{11} & \beta_{12} & \dots & \beta_{1m} \\ \vdots & \vdots & \ddots & \vdots \\ \beta_{r1} & \beta_{r2} & \dots & \beta_{rm} \end{bmatrix} \end{aligned} \quad (21)$$

$$= [\boldsymbol{\beta}_{(1)} \quad \vdots \quad \boldsymbol{\beta}_{(2)} \quad \vdots \quad \cdots \quad \vdots \quad \boldsymbol{\beta}_{(m)}]$$

and

$$\begin{aligned} \boldsymbol{\epsilon}_{(n \times m)} &= \begin{bmatrix} \epsilon_{11} & \epsilon_{12} & \cdots & \epsilon_{1m} \\ \epsilon_{21} & \epsilon_{22} & \cdots & \epsilon_{2m} \\ \vdots & \vdots & & \vdots \\ \epsilon_{n1} & \epsilon_{n2} & \cdots & \epsilon_{nm} \end{bmatrix} \\ &= [\boldsymbol{\epsilon}_{(1)} \quad \vdots \quad \boldsymbol{\epsilon}_{(2)} \quad \vdots \quad \cdots \quad \vdots \quad \boldsymbol{\epsilon}_{(m)}] \end{aligned} \quad (22)$$

Stated simply, the i th response $Y_{(i)}$ follows the linear regression model (see Table 3)

$$\mathbf{Y}_{(i)} = \mathbf{Z}\boldsymbol{\beta}_{(i)} + \boldsymbol{\epsilon}_{(i)}, \quad i = 1, 2, \dots, m \quad (23)$$

with $\text{Cov}(\boldsymbol{\epsilon}_{(i)}) = \sigma_{ii}\mathbf{I}$. However, the errors for *different* responses on the *same* trial can be correlated.

The m observations on the j th trial have covariance matrix $\boldsymbol{\Sigma} = \{\sigma_{ik}\}$, but observations from different trials are uncorrelated. Here $\boldsymbol{\beta}$ and $\boldsymbol{\Sigma}$ are matrices of unknown parameters and the design matrix $\mathbf{Z}$ has the j th row $[z_{j0}, \dots, z_{jr}]$.

Given the outcomes $\mathbf{Y}$ and the values of the predictor variables $\mathbf{Z}$, we determine the least-squares estimates $\hat{\boldsymbol{\beta}}_{(i)}$ exclusively from the observations, $\mathbf{Y}_{(i)}$, on the i th response. Since

$$\hat{\boldsymbol{\beta}}_{(i)} = (\mathbf{Z}'\mathbf{Z})^{-1}\mathbf{Z}'\mathbf{Y}_{(i)} \quad (24)$$

$$\begin{aligned} \hat{\boldsymbol{\beta}} &= [\hat{\boldsymbol{\beta}}_{(1)} \quad \vdots \quad \hat{\boldsymbol{\beta}}_{(2)} \quad \vdots \quad \cdots \quad \vdots \quad \hat{\boldsymbol{\beta}}_{(m)}] \\ &= (\mathbf{Z}'\mathbf{Z})^{-1}\mathbf{Z}'\mathbf{Y} \end{aligned} \quad (25)$$

Using the least-squares estimates $\hat{\boldsymbol{\beta}}$, we can form the matrices of

$$\text{Predicted values } \hat{\mathbf{Y}} = \mathbf{Z}\hat{\boldsymbol{\beta}} = \mathbf{Z}(\mathbf{Z}'\mathbf{Z})^{-1}\mathbf{Z}'\mathbf{Y} \quad (26)$$

$$\text{Residuals } \hat{\boldsymbol{\epsilon}} = \mathbf{Y} - \hat{\mathbf{Y}} = \mathbf{I} - \mathbf{Z}(\mathbf{Z}'\mathbf{Z})^{-1}\mathbf{Z}'\mathbf{Y} \quad (27)$$

Table 3 Multivariate linear regression model

with					
$E(\boldsymbol{\epsilon}_{(i)}) = \mathbf{0};$					
$\text{Cov}(\boldsymbol{\epsilon}_{(i)}, \boldsymbol{\epsilon}_{(k)}) = \sigma_{ik}\mathbf{I}, \quad i, k = 1, 2, \dots, m.$					
The m observations on the j th trial have covariance matrix $\boldsymbol{\Sigma} = \{\sigma_{ik}\}$, but observations from different trials are uncorrelated. Here $\boldsymbol{\beta}$ and $\boldsymbol{\Sigma}$ are matrices of unknown parameters and the design matrix $\mathbf{Z}$ has the j th row $[z_{j0}, \dots, z_{jr}]$.					

Example 2 Companies considering the purchase of a computer must first assess their future needs in order to determine the proper equipment. Data from several similar company sites can be used to develop a forecast equation of computer hardware requirements for, say, inventory management. The independent variables might include z_1 = customer orders and z_2 = add–delete items. The multivariate responses might include Y_1 = central processing unit (CPU) time and Y_2 = disc input/output capacity [10, Chapter 7].

Summary Remarks

Anderson [2, Section 8.7] derives test statistics and discusses the distribution theory for multivariate regression.

By allowing $\mathbf{Z}$ to have less than full rank, all fixed-effects MANOVA can be incorporated into the multivariate multiple regression framework. This unifying concept is also valuable in connecting ANOVA with the classical multiple linear regression model.

A regression model in which the $((r+1) \times m)$ coefficient matrix $\boldsymbol{\beta}$ is less than full rank is known as a *reduced-rank regression model*. This can arise in a variety of contexts, and can also be linked to the multivariate techniques of principal components and canonical correlation analysis. See reference [12] for a comprehensive discussion of multivariate reduced-rank regression.

Analysis of Covariance Structure

Principal Components

A principal component analysis is concerned with explaining the variance–covariance structure through a few *linear* combinations of the original variables. Its general objectives are (a) data reduction and (b) interpretation.

Although p components are required to reproduce the total system variability, often, much of this variability can be accounted for by a small number k of the principal components. If so, there is (almost) as much information in the k components as there is in the original p variables. The k principal components can then replace the initial p variables, and the original data set is reduced to one consisting of n measurements on k principal components.

Analyses of principal components are more of a means to an end than an end in themselves because they frequently serve as intermediate steps in much larger investigations. For example, principal components may be inputs to a multiple linear regression (as incorporated in the *partial least-squares* approach).

Algebraically, principal components are particular linear combinations of the p random variables $X_1, X_2, \dots, X_p$. Geometrically, these linear combinations represent the selection of a new coordinate system obtained by rotating the original system with $X_1, X_2, \dots, X_p$ as the coordinate axes. The new axes represent the directions with maximum variability and provide a simpler and more parsimonious description of the covariance structure.

Principal components depend solely on the covariance matrix Σ (or the correlation matrix ρ) of $X_1, X_2, \dots, X_p$. Their development does not require a multivariate normal assumption.

The first principal component is the linear combination with maximum variance. That is, it maximizes $\text{Var}(Y_1) = \mathbf{a}_1' \Sigma \mathbf{a}_1$, where the coefficient vector $\mathbf{a}_1$ is restricted to be of unit length. Therefore, we define first principal component = linear combination $\mathbf{a}_1' \mathbf{X}$ that maximizes

$$\text{Var}(\mathbf{a}_1' \mathbf{X}) \quad \text{subject to} \quad \mathbf{a}_1' \mathbf{a}_1 = 1 \quad (28)$$

second principal component = linear combination $\mathbf{a}_2' \mathbf{X}$ that maximizes

$$\text{Var}(\mathbf{a}_2' \mathbf{X}) \quad \text{subject to} \quad \mathbf{a}_2' \mathbf{a}_2 = 1 \quad (29)$$

and

$$\text{Cov}(\mathbf{a}_1' \mathbf{X}, \mathbf{a}_2' \mathbf{X}) = 0 \quad (30)$$

At the i th step, i th principal component = linear combination $\mathbf{a}_i' \mathbf{X}$ that maximizes

$$\text{Var}(\mathbf{a}_i' \mathbf{X}) \quad \text{subject to} \quad \mathbf{a}_i' \mathbf{a}_i = 1 \quad (31)$$

and

$$\text{Cov}(\mathbf{a}_i' \mathbf{X}, \mathbf{a}_k' \mathbf{X}) = 0 \quad \text{for} \quad k < i \quad (32)$$

Let Σ be the covariance matrix associated with the random vector $\mathbf{X}' = [X_1, X_2, \dots, X_p]$. Let Σ have the eigenvalue–eigenvector pairs $(\lambda_1, \mathbf{e}_1), (\lambda_2, \mathbf{e}_2), \dots, (\lambda_p, \mathbf{e}_p)$, where $\lambda_1 \geq \lambda_2 \geq \dots \geq \lambda_p \geq 0$. The i th principal component is given by

$$Y_i = \mathbf{e}_i' \mathbf{X} = e_{i1}X_1 + e_{i2}X_2 + \dots + e_{ip}X_p, \quad i = 1, 2, \dots, p \quad (33)$$

With these choices,

$$\text{Var}(Y_i) = \mathbf{e}_i' \Sigma \mathbf{e}_i = \lambda_i, \quad i = 1, 2, \dots, p \quad (34)$$

$$\text{Cov}(Y_i, Y_k) = \mathbf{e}_i' \Sigma \mathbf{e}_k = 0, \quad i \neq k \quad (35)$$

Therefore, the principal components are uncorrelated and have variances equal to the eigenvalues of Σ . If some λ_i are equal, the choices of the corresponding coefficient vectors $\mathbf{e}_i$, and hence of $\mathbf{Y}_i$ are not unique.

How do we summarize the sample variation in n measurements on p variables with a few judiciously chosen linear combinations?

Assume the data $\mathbf{x}_1, \mathbf{x}_2, \dots, \mathbf{x}_n$ represent n independent drawings from some p -dimensional population with mean vector μ and covariance matrix Σ . These data yield the sample mean vector $\bar{\mathbf{x}}$, the sample covariance matrix $\mathbf{S}$, and the sample correlation matrix $\mathbf{R}$. These quantities are substituted for the corresponding population quantities above to get *sample principal components*.

Example 3 The weekly rates of return for five stocks (Allied Chemical, DuPont, Union Carbide, Exxon, and Texaco) listed on the New York Stock Exchange were determined for the period January 1975–December 1976. The weekly rates of return are defined as (current Friday closing price – previous Friday closing price)/(previous Friday closing price) adjusted for stock splits and dividends. The observations in 100 successive weeks appear to be distributed independently, but the rates of return *across* stocks are correlated, since, as one expects, stocks tend to move together in response to general economic conditions.

Let $x_1, x_2, \dots, x_5$ denote observed weekly rates of return for Allied Chemical, DuPont, Union Carbide, Exxon, and Texaco, respectively. Then,

$$\bar{\mathbf{x}}' = [0.0054, 0.0048, 0.0057, 0.0063, 0.0037] \quad (36)$$

$$\mathbf{R} = \begin{bmatrix} 1.000 & 0.577 & 0.509 & 0.387 & 0.462 \\ 0.577 & 1.000 & 0.599 & 0.389 & 0.322 \\ 0.509 & 0.599 & 1.000 & 0.436 & 0.426 \\ 0.387 & 0.389 & 0.436 & 1.000 & 0.523 \\ 0.462 & 0.322 & 0.426 & 0.523 & 1.000 \end{bmatrix} \quad (37)$$

8 Multivariate Analysis

We note that $\mathbf{R}$ is the covariance matrix of the standardized observations

$$\begin{aligned} z_1 &= \frac{x_1 - \bar{x}_1}{\sqrt{s_{11}}}, \quad z_2 = \frac{x_2 - \bar{x}_2}{\sqrt{s_{22}}}, \quad \dots, \\ z_5 &= \frac{x_5 - \bar{x}_5}{\sqrt{s_{55}}} \end{aligned} \quad (38)$$

The eigenvalues and corresponding normalized eigenvectors of $\mathbf{R}$ were determined by a computer and are

$$\hat{\lambda}_1 = 2.857, \hat{\mathbf{e}}'_1 = [0.464, 0.457, 0.470, 0.421, 0.421] \quad (39)$$

$$\hat{\lambda}_2 = 0.809, \hat{\mathbf{e}}'_2 = [0.240, 0.509, 0.260, -0.526, -0.582] \quad (40)$$

$$\hat{\lambda}_3 = 0.540, \hat{\mathbf{e}}'_3 = [-0.612, 0.178, 0.335, 0.541, -0.435] \quad (41)$$

$$\hat{\lambda}_4 = 0.452, \hat{\mathbf{e}}'_4 = [0.387, 0.206, -0.662, 0.472, -0.382] \quad (42)$$

$$\hat{\lambda}_5 = 0.343, \hat{\mathbf{e}}'_5 = [-0.451, 0.676, -0.400, -0.176, 0.385] \quad (43)$$

Using the standardized variables, we obtain the first two sample principal components

$$\hat{y}_1 = \hat{\mathbf{e}}'_1 \mathbf{z} = 0.464z_1 + 0.457z_2 + 0.470z_3 + 0.421z_4 + 0.421z_5 \quad (44)$$

$$\hat{y}_2 = \hat{\mathbf{e}}'_2 \mathbf{z} = 0.240z_1 + 0.509z_2 + 0.260z_3 - 0.526z_4 - 0.582z_5 \quad (45)$$

These components, which account for

$$\begin{aligned} \left(\frac{\hat{\lambda}_1 + \hat{\lambda}_2}{p} \right) 100\% &= \left(\frac{2.857 + 0.809}{5} \right) 100\% \\ &= 73\% \end{aligned} \quad (46)$$

of the total (standardized) sample variance, have interesting interpretations. The first component is a (roughly) equally weighted sum or “index”, of the five stocks. This component might be called a *general stock-market component* or simply a *market component*. (In fact, at the time the data were

collected, these five stocks were included in the Dow–Jones Industrial Average.)

The second component represents a contrast between the chemical stocks (Allied Chemical, DuPont, and Union Carbide) and the oil stocks (Exxon and Texaco). It might be called an *industry component*. Thus, most of the variation in these stock returns is due to market activity and uncorrelated industry activity.

The remaining components are not easy to interpret and, collectively, represent variation that is probably specific to each stock. In any event, they do not explain much of the total sample variance.

Factor Analysis

The essential purpose of factor analysis is to describe, if possible, the covariance relationships among many variables in terms of a few underlying, but unobservable, random quantities called *factors*. Basically, the factor model is motivated by the following argument. Suppose variables can be grouped by their correlations. That is, all variables within a particular group are highly correlated among themselves but have relatively small correlations with variables in a different group. It is conceivable that each group of variables represents a single underlying construct or factor that is responsible for the observed correlations. For example, correlations from the group of test scores in Classics, French, English, Mathematics, and Music collected by Spearman suggested an underlying “intelligence” factor. A second group of variables, perhaps representing physical-fitness scores, might correspond to another factor. It is this type of structure that factor analysis seeks to confirm.

Factor analysis can be considered an extension of principal component analysis. Both can be viewed as attempts to approximate the covariance matrix Σ . The approximation based on the factor analysis model is more elaborate; the primary question is whether the data are consistent with a prescribed structure.

The observable random vector $\mathbf{X}$ with p components has mean μ and covariance matrix Σ . The factor model postulates that $\mathbf{X}$ is linearly dependent on a few unobservable random variables $F_1, F_2, \dots, F_m$, called *common factors* and p additional sources of variation $\epsilon_1, \epsilon_2, \dots, \epsilon_p$, called *errors* or, sometimes,

specific factors. In particular, the factor analysis model is

$$\begin{aligned} X_1 - \mu_1 &= l_{11}F_1 + l_{12}F_2 + \cdots + l_{1m}F_m + \epsilon_1 \\ X_2 - \mu_2 &= l_{21}F_1 + l_{22}F_2 + \cdots + l_{2m}F_m + \epsilon_2 \\ &\vdots \\ X_p - \mu_p &= l_{p1}F_1 + l_{p2}F_2 + \cdots + l_{pm}F_m + \epsilon_p \end{aligned} \quad (47)$$

or, in matrix notation,

$$\underset{(p \times 1)}{\mathbf{X}} - \underset{(p \times 1)}{\boldsymbol{\mu}} = \underset{(p \times m)}{\mathbf{L}} \underset{(m \times 1)}{\mathbf{F}} + \underset{(p \times 1)}{\boldsymbol{\epsilon}} \quad (48)$$

The coefficient l_{ij} is the *loading* of the i th variable on the j th factor, so the matrix $\mathbf{L}$ is the *matrix of factor loadings*. Note that the i th specific factor ϵ_i is associated only with the i th response X_i . The p deviations $X_1 - \mu_1, X_2 - \mu_2, \dots, X_p - \mu_p$ are expressed in terms of $p + m$ variables $F_1, F_2, \dots, F_m, \epsilon_1, \epsilon_2, \dots, \epsilon_p$, which are unobservable.

With so many unobservable quantities, a direct verification of the factor model from observations on $X_1, X_2, \dots, X_p$ is hopeless. However, with some additional assumptions about the random vectors $\mathbf{F}$ and $\boldsymbol{\epsilon}$, the preceding model implies certain covariance relationships that can be checked. It follows immediately from the factor model that

1. $\text{Cov}(\mathbf{X}) = \mathbf{L}\mathbf{L}' + \boldsymbol{\Psi}$, or

$$\text{Var}(X_i) = l_{i1}^2 + \cdots + l_{im}^2 + \psi_i \quad \text{and} \quad (49)$$

$$\text{Cov}(X_i, X_k) = l_{i1}l_{k1} + \cdots + l_{im}l_{km} \quad (50)$$

2. $\text{Cov}(\mathbf{X}, \mathbf{F}) = \mathbf{L}$, or $\text{Cov}(X_i, F_j) = l_{ij}$.

That portion of the variance of the i th variable contributed by the m common factors is called the i th *communality*. The portion of $\text{Var}(X_i) = \sigma_{ii}$ due to the specific factor is often called the *uniqueness* or *specific variance*. Denoting the i th communality by h_i^2 ,

$$\begin{aligned} \underbrace{\sigma_{ii}}_{\text{Var}(X_i)} &= \underbrace{l_{i1}^2 + l_{i2}^2 + \cdots + l_{im}^2}_{\text{communality}} + \underbrace{\psi_i}_{\text{specific variance}} \end{aligned} \quad (51)$$

or $h_i^2 = l_{i1}^2 + l_{i2}^2 + \cdots + l_{im}^2$, and $\sigma_{ii} = h_i^2 + \psi_i$, $i = 1, 2, \dots, p$. The i th communality is the sum of squares of the loadings of the i th variable on the m common factors.

Given observations $\mathbf{x}_1, \mathbf{x}_2, \dots, \mathbf{x}_n$ on p generally correlated variables, factor analysis seeks to answer the question: Does the factor model (see Table 4), with a small number of factors, adequately represent the data? In essence, we tackle this statistical model-building problem by trying to verify covariance relationships 1 and 2.

The sample covariance matrix $\mathbf{S}$ is an estimator of the unknown population covariance matrix $\boldsymbol{\Sigma}$. If the off-diagonal elements of $\mathbf{S}$ are small or those of the sample correlation matrix $\mathbf{R}$ essentially zero, the variables are not related and a factor analysis will not prove useful. In these circumstances, the *specific* factors play the dominant role, whereas the major aim of the factor analysis is to determine a few important *common* factors.

If $\boldsymbol{\Sigma}$ appears to deviate significantly from a diagonal matrix, then a factor model can be entertained. The initial problem is one of estimating the factor loadings l_{ij} and specific variances ψ_i . (Methods of **estimation** are discussed, for example, in references [5, Section 5.4; 7, Section 7.3; 13, Chapter 9].)

Table 4 Orthogonal factor model with m common factors

$\underset{(p \times 1)}{\mathbf{X}} = \underset{(p \times 1)}{\boldsymbol{\mu}} + \underset{(p \times m)}{\mathbf{L}} \underset{(m \times 1)}{\mathbf{F}} + \underset{(p \times 1)}{\boldsymbol{\epsilon}}$
$\mu_i = \text{mean of variable } i$
$\epsilon_i = i\text{th specific factor}$
$F_j = j\text{th common factor}$
$l_{ij} = \text{loading of the } i\text{th variable on the } j\text{th factor}$
The unobservable random vectors $\mathbf{F}$ and $\boldsymbol{\epsilon}$ satisfy
$\mathbf{F}$ and $\boldsymbol{\epsilon}$ are independent.
$E(\mathbf{F}) = \mathbf{0}, \text{Cov}(\mathbf{F}) = \mathbf{I}.$
$E(\boldsymbol{\epsilon}) = \mathbf{0}, \text{Cov}(\boldsymbol{\epsilon}) = \boldsymbol{\Psi},$ where $\boldsymbol{\Psi}$ is a diagonal matrix.

All factor loadings obtained from the initial loading by an orthogonal transformation have the same ability to reproduce the covariance (or correlation) matrix. From matrix algebra, we know that an orthogonal transformation corresponds to a rigid rotation (or reflection) of the coordinate axes. For this reason, an orthogonal transformation of the factor loadings and the implied orthogonal transformation of the factors is called *factor rotation*.

If $\hat{\mathbf{L}}$ is the $p \times m$ matrix of estimated factor loadings obtained by any method, then

$$\hat{\mathbf{L}}^* = \hat{\mathbf{L}}\mathbf{T}, \quad \text{where} \quad \mathbf{T}\mathbf{T}' = \mathbf{T}'\mathbf{T} = \mathbf{I} \quad (52)$$

is a $p \times m$ matrix of “rotated” loadings. Moreover, the estimated covariance (or correlation) matrix remains unchanged, since

$$\hat{\mathbf{L}}\hat{\mathbf{L}}' + \hat{\Psi} = \hat{\mathbf{L}}\mathbf{T}\mathbf{T}'\hat{\mathbf{L}} + \hat{\Psi} = \hat{\mathbf{L}}^*\hat{\mathbf{L}}^{*'} + \hat{\Psi} \quad (53)$$

The residual matrix $\mathbf{S} - \hat{\mathbf{L}}\hat{\mathbf{L}}' - \hat{\Psi} = \mathbf{S} - \hat{\mathbf{L}}^*\hat{\mathbf{L}}^{*'} - \hat{\Psi}$ also remains unchanged after rotation. Moreover, the specific variances ψ_i and hence the communalities $\hat{h}_i^2$ are unaltered. Therefore, from a mathematical viewpoint, it is immaterial whether $\hat{\mathbf{L}}$ or $\hat{\mathbf{L}}^*$ is obtained.

Since the original loadings may not be readily interpretable, the usual practice is to rotate them until a “simple structure” is achieved. The rationale is very much akin to sharpening the focus of a microscope in order to see the detail more clearly.

Ideally, we should like to see a pattern of loadings such that each variable loads highly on a single factor and has small-to-moderate loadings on the remaining factors. It is not always possible to get this simple structure.

Kaiser [14] has suggested an analytical measure of simple structure known as the *varimax* (or *normal varimax*) criterion. Define $\tilde{l}_{ij}^* = \hat{l}_{ij}^*/\hat{h}_i$ to be the final rotated coefficients scaled by the square root of the communalities. The (normal) varimax procedure selects the orthogonal transformation $\mathbf{T}$ that makes

$$V = \frac{1}{p} \sum_{j=1}^m \left[\sum_{i=1}^p \tilde{l}_{ij}^{*4} - \left(\sum_{i=1}^p \tilde{l}_{ij}^{*2} \right)^2 / p \right] \quad (54)$$

as large as possible.

Effectively maximizing V corresponds to “spreading out” the squares of the loadings on each factor as much as possible. Therefore, we hope to find groups

of large and negligible coefficients in any *column* of the rotated loadings matrix $\mathbf{L}^*$.

In factor analysis, interest is usually centered on the parameters in the factor model. However, the estimated values of the common factors, called *factor scores*, may also be required. Often, these quantities are used for diagnostic purposes as well as inputs to a subsequent analysis. (See references [4, Section 9.5; 7, Section 7.8; 8, Section 13.6] for further discussion of factor scores.)

Example 4 Beginning with correlations between the scores of the Olympic decathlon events, a factor analysis can be employed to see if the 10 events can be explained in terms of two, three, or four underlying “physical” factors. One interesting study of this kind [15] found that the four factors “explosive arm strength”, “explosive leg strength”, “running speed”, and “running endurance” represented several years of decathlon data quite well.

Canonical Correlations and Variables

Canonical correlation analysis seeks to identify and quantify the associations between two sets of variables. Harold Hotelling [16], who initially developed the technique, provided the example of relating arithmetic speed and arithmetic power to reading speed and reading power. Other examples include relating governmental policy variables to economic goal variables and relating college “performance” variables with precollege “achievement” variables.

Canonical correlation analysis focuses on the correlation between a linear combination of the variables in one set and a linear combination of the variables in another set. When the association between the two sets is expected to be unidirectional – from one set to the other – we label one set the *independent* or *predictor* variables and the other set the *dependent* or *criterion* variables.

The idea of canonical correlation analysis is to first determine the pair of linear combinations having the largest correlation. Next, one determines the pair of predictor set/criterion set linear combinations having the largest correlation among all pairs uncorrelated with the initially selected pair. The process continues by selecting, at each stage, the pair of predictor set/criterion set linear combinations having largest correlation among all pairs that are uncorrelated with the preceding choices. The pairs of linear

combinations are the *canonical variables* and their correlations are *canonical correlations*. The following discussion gives the necessary details for obtaining the canonical variables and their correlations. In practice, sample covariance matrices are substituted for the corresponding population quantities, yielding sample canonical variables and sample canonical correlations.

Suppose $p \leq q$, and let the random vectors

$$\begin{matrix} \mathbf{X}_1 & \text{and} & \mathbf{X}_2 \\ (p \times 1) & & (q \times 1) \end{matrix}$$

have

$$\text{Cov}(\mathbf{X}_1) = \boldsymbol{\Sigma}_{11}, \text{Cov}(\mathbf{X}_2) = \boldsymbol{\Sigma}_{22} \quad (55)$$

$(p \times p) \quad (q \times q)$

and

$$\text{Cov}(\mathbf{X}_1, \mathbf{X}_2) = \boldsymbol{\Sigma}_{12} \quad (56)$$

$(p \times q)$

For coefficient vectors,

$$\begin{matrix} \mathbf{a} & \text{and} & \mathbf{b} \\ (p \times 1) & & (q \times 1) \end{matrix}$$

form the linear combinations $U = \mathbf{a}'\mathbf{X}_1$ and $V = \mathbf{b}'\mathbf{X}_2$. Then

$$\text{Max}_{\mathbf{a}, \mathbf{b}} \text{Corr}(U, V) = \rho_1^* \quad (57)$$

attained by the linear combination (first canonical variate pair)

$$U_1 = \mathbf{a}'_1 \mathbf{X}_1 \quad \text{and} \quad V_1 = \mathbf{b}'_1 \mathbf{X}_2 \quad (58)$$

The k th pair of canonical variates, $k = 2, 3, \dots, p$,

$$U_k = \mathbf{a}'_k \mathbf{X}_1 \quad \text{and} \quad V_k = \mathbf{b}'_k \mathbf{X}_2 \quad (59)$$

maximize

$$\text{Corr}(U_k, V_k) = \rho_k^* \quad (60)$$

among those linear combinations uncorrelated with the preceding $1, 2, \dots, k-1$ canonical variables.

The canonical variates have the following properties:

$$\text{Var}(U_k) = \text{Var}(V_k) = 1 \quad (61)$$

$$\text{Cov}(U_k, U_l) = \text{Corr}(U_k, U_l) = 0, \quad k \neq l \quad (62)$$

$$\text{Cov}(V_k, V_l) = \text{Corr}(V_k, V_l) = 0, \quad k \neq l \quad (63)$$

$$\text{Cov}(U_k, V_l) = \text{Corr}(U_k, V_l) = 0, \quad k \neq l \quad (64)$$

for $k, l = 1, 2, \dots, p$.

In general, canonical variables are artificial; they have no physical meaning. If the original variables $\mathbf{X}_1$ and $\mathbf{X}_2$ are used, the canonical coefficients $\mathbf{a}$ and $\mathbf{b}$ have units proportional to those of the $\mathbf{X}_1$ and $\mathbf{X}_2$ sets. If the original variables are standardized to have zero means and unit variances, the canonical coefficients have no units of measurement, and they must be interpreted in terms of the standardized variables.

Classification and Grouping Techniques

Discriminant Analysis and Classification

Discriminant analysis and classification are multivariate techniques concerned with *separating* distinct sets of objects (or observations) and with *allocating* new objects (observations) to previously defined groups. Discriminant analysis is rather exploratory in nature. As a separating procedure, it is often employed on a one-time basis in order to investigate observed differences when causal relationships are not well understood. Classification procedures are less exploratory in the sense that they lead to well-defined rules, which can be used for assigning new objects. Classification ordinarily requires more problem structure than discrimination.

Thus, the immediate goals of discrimination and classification, respectively, are

1. To describe either graphically (in three or fewer dimensions) or algebraically, the differential features of objects (observations) from several known collections (populations). We try to find “discriminants” whose numerical values are such that the collections are separated as much as possible.
2. To sort objects (observations) into two or more labeled classes. The emphasis is on deriving a rule that can be used to assign a *new* object to the labeled classes optimally.

To fix ideas, we will list situations in which one may be interested in (a) separating two classes of objects, or (b) assigning a new object to one of the two classes (or both). It is convenient to label the classes π_1 and π_2 . The objects are ordinarily separated or classified on the basis of measurements, for instance, on p associated random variables $\mathbf{X}' = [X_1, X_2, \dots, X_p]$. The observed values of $\mathbf{X}$ differ to some extent from one class to the other. We can

Populations π_1 and π_2	Measured variables $\mathbf{X}$
Solvent and distressed property-liability insurance companies	Total assets, cost of stocks and bonds, market value of stocks and bonds, loss expenses, surplus, amount of premiums written
Federalist papers written by James Madison and those written by Alexander Hamilton	Frequencies of different words and length of sentences
Purchasers of a new product and laggards (those “slow” to purchase)	Education, income, family size, amount of previous brand switching
Alcoholics and nonalcoholics	Activity of monoamine oxidase enzyme, activity of adenylate cyclase enzyme

think of the totality of values from the first class as being the population of $\mathbf{x}$ values for π_1 and those from the second class as the population of $\mathbf{x}$ values for π_2 . These two populations can then be described by probability density functions $f_1(\mathbf{x})$ and $f_2(\mathbf{x})$, and, consequently, we can talk of assigning observations to populations or objects to classes interchangeably.

You may wonder at this point how it is we *know* some observations belong to a particular population but we are unsure about others. (This, of course, is what makes classification a problem!) There are several conditions that can give rise to this apparent anomaly.

- Incomplete knowledge of future performance.
- “Perfect” information requires destroying object.
- Unavailable or expensive information.

It should be clear that classification rules cannot usually provide an error-free method of assignment. This is because there may not be a clear distinction between the measured characteristics of the populations; that is, the groups may overlap. It is then possible, for example, to incorrectly classify a π_2 object as belonging to π_1 or a π_1 object as belonging to π_2 .

For a discussion of discriminant analysis and subsequent classification procedures, see references [2, Chapter 6; 4, Chapter 11; 5, Chapter 6]. Since the literature on this subject is large, we simply display

below the “best” allocation rule for two multivariate normal populations with a common covariance matrix Σ . In practice, sample quantities replace the corresponding population quantities.

Let μ_1 and μ_2 be the two population mean vectors, $c(1|2)$ the cost of incorrectly assigning a population 2 observation to population 1, $c(2|1)$ the cost of incorrectly assigning a population 1 observation to population 2, p_1 the “prior” probability of population 1, and p_2 the “prior” probability of population 2, then we allocate $\mathbf{x}$ to π_1 if

$$(\mu_1 - \mu_2)' \Sigma^{-1} \mathbf{x} - \frac{1}{2}(\mu_1 - \mu_2)' \Sigma^{-1} (\mu_1 + \mu_2) \geq \ln \left[\frac{c(1|2)}{c(2|1)} \left(\frac{p_2}{p_1} \right) \right] \quad (65)$$

Allocate $\mathbf{x}$ to π_2 otherwise.

The first term, $y = (\mu_1 - \mu_2)' \Sigma^{-1} \mathbf{x}$, above is *Fisher's linear discriminant function*. (Fisher actually developed the sample version $\hat{y} = (\bar{\mathbf{x}}_1 - \bar{\mathbf{x}}_2)' \mathbf{S}_{\text{pooled}}^{-1} \mathbf{x}$, where $\mathbf{S}_{\text{pooled}}$ is the pooled sample covariance matrix.) Assuming a common population covariance matrix, it is the linear function $\mathbf{a}'\mathbf{x}$ with $\mathbf{a} \propto (\mu_1 - \mu_2)' \Sigma^{-1}$ that maximizes the separation between the two populations, as measured by

$$\frac{(\mu_{1y} - \mu_{2y})^2}{\sigma_y^2} = \frac{(\mathbf{a}'\mu_1 - \mathbf{a}'\mu_2)^2}{\mathbf{a}'\Sigma\mathbf{a}} \quad (66)$$

One important way of judging the performance of any classification procedure is to calculate its “error rates”, or misclassification probabilities. When the forms of the parent populations are known completely, misclassification probabilities can be calculated with relative ease. Because parent populations are rarely known, one must concentrate on the error rates associated with the sample classification function.

Finally, it should be intuitive that good classification (low error rates) will depend on the separation of the populations. The farther apart the groups, the more likely it is that a *useful* classification rule can be developed.

Fisher also proposed a several-population extension of his discriminant method. The motivation behind Fisher discriminant analysis is the need to obtain a reasonable representation of the populations that involves only a *few* linear combinations of the observations, such as $\mathbf{a}_1'\mathbf{x}$, $\mathbf{a}_2'\mathbf{x}$, and $\mathbf{a}_3'\mathbf{x}$. His approach

has several advantages when one is interested in *separating* several populations for visual inspection or graphically descriptive purposes. It allows for the following:

1. Convenient representations of the g populations that reduce the dimension from a very large number of characteristics to a relatively few linear combinations. Of course, some information – needed for optimal classification – may be lost unless the population means lie completely in the lower-dimensional space selected.
2. Plotting of the means of the first two or three linear combinations (discriminants). This helps display the relationships and possible groupings of the populations.
3. Scatterplots of the sample values of the first two discriminants, which can indicate **outliers*** or other abnormalities in the data. (See references [1, Chapter 4; 4, Section 11.7; 17, Chapter 2] for examples of low-dimensional representations.)

Summary Remarks

The linear discriminant functions that we have presented can arise from a multivariate multiple linear regression model with the response variable vector containing binary categorical variables representing the different groups.

Other, typically computer intensive, procedures are available for discrimination and classification. These include logistic regression, classification trees, **neural networks**, and support vector machines. A good reference for these and related methods is [1].

Clustering and Graphical Procedures

Rudimentary, exploratory procedures are often quite helpful in understanding the complex nature of multivariate relationships. Searching the data for a structure of “natural” groupings is an important exploratory technique. Groupings can provide an informal means for assessing dimensionality, identifying outliers, and suggesting interesting hypotheses concerning relationships.

Grouping, or clustering, is distinct from the classification methods discussed earlier. Classification pertains to a *known* number of groups, and the operational objective is to assign new observations to one

of these groups. Cluster analysis is a more primitive technique in that no assumptions are made concerning the number of groups or the group structure. Grouping is done on the basis of similarities or distances (dissimilarities). The inputs required are similarity measures or data from which similarities can be computed. Good references on clustering include [1, Section 14.3; 4, Chapter 7; 18, 19].

Clustering and Lower-Dimensional Representations

Even without the precise notion of a natural grouping, we are often able to cluster objects in two- or three-dimensional scatter plots by eye. To take advantage of the mind’s ability to group similar objects, several graphical procedures have been developed for depicting high-dimensional observations in two dimensions. Boxes, glyphs, stars, Andrews plots, and Chernoff faces are among the methods that produce two-dimensional “pictures” of multivariate data.

Two-dimensional scatter plots of high-dimensional data can be constructed using principal component axes, or discriminant score axes, or canonical variate axes. In doing so, there is always some information lost. In contrast to this activity, multidimensional scaling seeks to directly “fit” the original data into a low-dimensional space such that any distortion caused by a lack of dimensionality is minimized.

A biplot is a two-dimensional graphical representation of the information in the $n \times p$ data matrix. Correspondence analysis is a graphical procedure for representing association in a two-way table of frequencies or counts.

Extensions of two-dimensional principal component representations of data such as self-organizing maps and principal curves and surfaces are discussed in reference [1, Chapter 14].

Multivariate Methods and Data Mining

Data mining (ref. to Data Mining Review article in CIM section) refers to the process of discovering associations and relationships in very large data sets (perhaps several terabytes of data). Data mining is not possible without appropriate software and fast computers. Many of the multivariate methods discussed here, along with algorithms developed in the machine learning and artificial intelligence fields, play important roles in data mining. Data mining

has helped to identify new chemical compounds for prescription drugs, detect fraudulent claims and purchases, create and maintain individual customer relationships, design better engines, improve process control, and develop effective credit scoring rules.

Probability Theory

Introduction

Probability theory provides a mathematical framework for the description of phenomena whose outcomes are not deterministic but rather are subject to chance. This framework, historically motivated by a frequency interpretation of probability, is provided by a formal set of three innocent-looking axioms and the consequences thereof. These are far-reaching, and a rich and diverse theory has been developed. It provides a flexible and effective model of physical reality and furnishes, in particular, the mathematical theory needed for the study of the discipline of statistics.

The Formal Framework

Elementary (nonmeasure theoretic) treatments of probability can readily deal with situations in which the set of distinguishable outcomes of an experiment subject to chance (called *elementary events*) is finite. This encompasses most simple gambling situations, for example.

Let the set of all elementary events be Ω (called the *sample space*) and let $\mathcal{F}$ be the Boolean field of subsets of Ω (meaning just that (a) $A \in \mathcal{F}$ implies that $\bar{A} \in \mathcal{F}$, the bar denoting complementation with respect to Ω and (b) $A_1, A_2 \in \mathcal{F}$ implies that $A_1 \cup A_2 \in \mathcal{F}$). Then the probability P is a set function on $\mathcal{F}$ satisfying the axioms:

Axiom 1 $P(A) \geq 0, A \in \mathcal{F}$.

Axiom 2 If $A_1, A_2 \in \mathcal{F}$ and $A_1 \cap A_2 = \emptyset$ (the empty set), then

$$P(A_1 \cup A_2) = P(A_1) + P(A_2) \quad (1)$$

Axiom 3 $P(\Omega) = 1$.

These axioms enable probabilities to be assigned to events in simple games of chance. For example, in the toss of an ordinary six-sided die, Ω consists of six equiprobable elementary events and for $A \in \mathcal{F}$, $P(A) = n(A)/6$, where $n(A)$ is the number of elementary events in A .

The formulation above can be extended straightforwardly to the case where the number of elementary

events in the sample space is at most countable, by extending Axiom 2 to deal with countable unions of disjoint sets. However, a full measure-theoretic formulation is necessary to deal with general sample spaces Ω and to provide a framework which is rich enough for a comprehensive study of limit results on combinations of events (sets).

The measure-theoretic formulation has a very similar appearance to the elementary version. We start from a general sample space Ω and let $\mathcal{F}$ be the Borel σ -field of subsets of Ω (meaning that (a) $A \in \mathcal{F}$ implies that $\bar{A} \in \mathcal{F}$ and (b) $A_i \in \mathcal{F}, 1 \leq i < \infty$, implies that $\bigcup_{i=1}^{\infty} A_i \in \mathcal{F}$). Then as axioms for the probability measure P we have Axioms 1 and 3 as before, while Axiom 2 is replaced by:

Axiom 2' If $A_i \in \mathcal{F}, 1 \leq i < \infty$, and $A_i \cap A_j = \emptyset, i \neq j$, then

$$P\left(\bigcup_{i=1}^{\infty} A_i\right) = \sum_{i=1}^{\infty} P(A_i) \quad (2)$$

The triplet $(\Omega, \mathcal{F}, P)$ is called a *probability space*. This framework is due to Kolmogorov [1] in 1933 and is very widely accepted, although some authors reject the countable additivity Axiom 2' and rely on the finite additivity version (Axiom 2) (e.g., Dubins and Savage [2]). An extension of the Kolmogorov theory in which unbounded measures are allowed and conditional probabilities are taken as the fundamental concept has been provided by Rényi [3, Chapter 2]. For $A, B \in \mathcal{F}$ with $P(B) > 0$, the conditional probability of A given B is defined as $P(A|B) = P(A \cap B)/P(B)$.

Suppose that the sample space Ω has points ω . A real-valued function $X(\omega)$ defined on the probability space $(\Omega, \mathcal{F}, P)$ is called a *random variable* (or, in the language of measure theory, $X(\omega)$ is a *measurable function*) if the set $\{\omega : X(\omega) \leq x\}$ belongs to $\mathcal{F}$ for every $x \in \mathbb{R}$ (the real line). Sets of the form $\{\omega : X(\omega) \leq x\}$ are usually written as $\{X \leq x\}$ for convenience and we shall follow this practice. Random variables and their relationships are the principal objects of study in much of probability and statistics.

Important Concepts

Each random variable X has an associated *distribution function* defined for each real x by

$$F(x) = P(X \leq x) \quad (3)$$

2 Probability Theory

The function F is nondecreasing, right continuous, and has at most a countable set of points of discontinuity. It also uniquely specifies the probability measure that X induces on the real line.

Random variables are categorized as having a discrete distribution if the corresponding distribution function is a step function and as having a continuous distribution if it is continuous. Most continuous distributions of practical interest are absolutely continuous, meaning that the distribution function $F(x)$ has a representation of the form

$$F(x) = \int_{-\infty}^x f(u) du \quad (4)$$

for some $f \geq 0$; f is called the **probability density function**.

A relatively small number of families of distributions are widely used in applications of probability theory (see **Probability Density Functions**). Among the most important are the binomial, which is discrete and for which

$$P(X = r) = \binom{n}{r} p^r (1-p)^{n-r}, \quad 0 \leq r \leq n, \quad 0 < p < 1 \quad (5)$$

and the (unit) normal, which is absolutely continuous and for which

$$P(X \leq x) = (2\pi)^{-1/2} \int_{-\infty}^x e^{-(1/2)u^2} du \quad -\infty < x < \infty \quad (6)$$

The binomial random variable represents the numbers of successful outcomes in n trials, repeated under the same conditions, where the probability of success in each individual trial is p . Normal distributions, or close approximations thereto, occur widely in practice, for example, in such measurements as heights or weights or examination scores, where a large number of individuals are involved.

Two other particularly important distributions are the Poisson, for which

$$P(X = r) = e^{-\lambda} \lambda^r / r! \quad r = 0, 1, 2, \dots, \quad \lambda > 0 \quad (7)$$

and the exponential, for which

$$P(X \leq x) = \lambda \int_0^x e^{-\lambda u} du, \quad x > 0, \quad \lambda > 0 \\ = 0 \text{ otherwise} \quad (8)$$

These commonly occur in situations of rare events and as waiting times between phenomena, respectively.

A sequence of random variables $\{X_1, X_2, \dots\}$ defined on the same probability space is called a *stochastic process*. For a finite collection of such random variables $\{X_1, X_2, \dots, X_m\}$ we can define the joint distribution function

$$F(x_1, x_2, \dots, x_m) \\ = P(X_1 \leq x_1, X_2 \leq x_2, \dots, X_m \leq x_m) \quad (9)$$

for $x_i \in \mathbb{R}$, $1 \leq i \leq m$, and the random variables are said to be *independent* if

$$P(X_1 \leq x_1, \dots, X_m \leq x_m) \\ = P(X_1 \leq x_1) \cdots P(X_m \leq x_m) \quad (10)$$

for all $x_1, \dots, x_m$ (see **Dependence**). Independence is often an essential basic property and much of probability and statistics is concerned with random sampling, namely independent observations (random variables) with identical distributions.

One step beyond independence is the Markov chain $\{X_1, X_2, \dots\}$, in which case

$$P(X_m \leq x_m | X_1 = i_1, \dots, X_n = i_n) \\ = P(X_m \leq x_m | X_n = i_n) \quad (11)$$

for any $n < m$ and all $i_1, \dots, i_n$ and x_m . That is, dependence on a past history involves only the most recent of the observations. Such random sequences with a natural timescale belong to the domain of stochastic processes; see **Markov Processes**.

Considerable summary information about random variables and their distributions is contained in quantities called *moments* (see **Moments**). For a random variable X with distribution function F , the r th *moment* ($r > 0$) is defined by

$$EX^r = \int_{-\infty}^{\infty} x^r dF(x) \quad (12)$$

provided that $\int_{-\infty}^{\infty} |x|^r dF(x) < \infty$. $E|X|^r$ is called the r th *absolute moment*. The operator E is called *expectation* (see **Expectation**) and the first moment ($r = 1$) is termed the *mean*. Moments about the mean $E(X - EX)^r$, $r = 2, 3, \dots$ are widely used and $E(X - EX)^2$ is termed the *variance* (see **Variance**) of X , while $(E(X - EX)^2)^{1/2}$ is its *standard deviation*. The mean and variance of X are, respectively, measures of the location and spread of its distribution.

Convergence

Much of probability theory is concerned with the limit behavior of sequences of random variables or their distributions. The great diversity of possible probabilistic behavior when the **sample size** is small is often replaced by unique and well-defined probabilistic behavior for large sample sizes. In this lies the great virtue of the limit theory: statistical regularity emerging out of statistical chaos as the sample size increases.

A sequence of random variables $\{X_n\}$ is said to converge *in distribution* (or *in law*) to that of a random variable X (written $X_n \xrightarrow{d} X$) if the sequence of distribution functions $\{F_n(x) = P(X_n \leq x)\}$ converges to the distribution function $F(x) = P(X \leq x)$ at all points x of continuity of F .

Convergence in distribution does not involve the random variables explicitly, only their distributions. Other commonly used modes of convergence are the following:

1. $\{X_n\}$ converges *in probability* to X (written $X_n \xrightarrow{P} X$) if, for every $\epsilon > 0$,

$$\lim_{n \rightarrow \infty} P(|X_n - X| > \epsilon) = 0 \quad (13)$$

2. For $r > 0$, $\{X_n\}$ converges *in the mean of order r* to X (written $X_n \xrightarrow{r} X$) if

$$\lim_{n \rightarrow \infty} E|X_n - X|^r = 0 \quad (14)$$

3. $\{X_n\}$ converges *almost surely* to X (written $X_n \xrightarrow{\text{a.s.}} X$) if for every $\epsilon > 0$,

$$\lim_{n \rightarrow \infty} P\left(\sup_{k \geq n} |X_k - X| > \epsilon\right) = 0 \quad (15)$$

It is not difficult to show that 2 implies 1, which in turn implies convergence in distribution while 3 implies 1. None of the converse implications hold in general.

Convergence in distribution is frequently established by the method of characteristic functions. The *characteristic function* of a random variable X with distribution function F is defined by

$$f(t) = Ee^{itX} = \int_{-\infty}^{\infty} e^{itx} dF(x) \quad (16)$$

where $i = \sqrt{-1}$. If $f_n(t)$ and $f(t)$ are, respectively, the characteristic functions of X_n and X , then $X_n \xrightarrow{d} X$ is equivalent to $f_n(t) \rightarrow f(t)$. Characteristic functions are particularly convenient for dealing with sums of independent random variables as a consequence of the multiplicative property

$$Ee^{it(X+Y)} = Ee^{itX} Ee^{itY} \quad (17)$$

for independent X and Y . They have been extensively used in most treatments of convergence in distribution for sums of independent random variables (the classical central limit problem). The basic central limit theorem (of which there are many generalizations) deals with independent and identically distributed random variables X_i with mean μ and variance σ^2 . It gives, upon writing $S_n = \sum_{i=1}^n X_i$, that

$$\begin{aligned} \lim_{n \rightarrow \infty} P(\sigma^{-1}n^{-1/2}(S_n - n\mu) \leq x) \\ = (2\pi)^{-1/2} \int_{-\infty}^x e^{-(1/2)u^2} du \end{aligned} \quad (18)$$

the limit being the distribution function of the unit normal law.

Convergence in probability results are often obtained with the aid of Markov's inequality

$$P(|X_n| > c) \leq c^{-r} E|X_n|^r \quad (19)$$

for $r > 0$ and a corresponding convergence in the r th mean result. The useful particular case $r = 2$ of Markov's inequality is ordinarily called *Chebyshev's inequality*. For example, in the notation of equation (20),

$$P(|n^{-1}S_n - \mu| > \epsilon) \leq \epsilon^{-2}n^{-2}E(S_n - n\mu)^2 \rightarrow 0 \quad (20)$$

4 Probability Theory

as $n \rightarrow \infty$, which is a version of the weak (see **Laws of Large Numbers**), $n^{-1}S_n \xrightarrow{P} \mu$.

Almost sure convergence results rely heavily on the Borel–Cantelli lemmas. These deal with a sequence of events (sets) $\{E_n\}$ and $E = \bigcap_{r=1}^{\infty} \bigcup_{n=r}^{\infty} E_n$, the set of elements common to infinitely many of the E_n . Then

1. $\sum P(E_n) < \infty$ implies that $P(E) = 0$.
2. $\sum P(E_n) = \infty$ and the events E_n are independent implies that $P(E) = 1$.

With the aid of 1, equation (21) can be strengthened to the strong *law of large numbers* (see **Laws of Large Numbers**),

$$n^{-1}S_n \xrightarrow{\text{a.s.}} \mu \quad (21)$$

as $n \rightarrow \infty$.

The strong law of large numbers embodies the idea of a probability as a strong limit of relative frequencies; if we set $X_i = I_i(A)$, the indicator function of the set A at the i th trial, then $\mu = P(A)$. This property is an important requirement of a physically realistic theory.

The law of large numbers, together with the central limit theorem, provides a basis for a fundamental piece of statistical theory. The former yields an estimator of the location parameter μ and the latter enables approximate *confidence intervals* (see **Confidence Intervals**) for μ to be prescribed and tests of hypotheses (see **Hypothesis Testing**) constructed.

Other Approaches

The discussion above is based on a frequency interpretation of probability, and this provides the richest theory. There are, however, significant limitations to a frequency interpretation in describing uncertainty in some contexts, and various other approaches have been suggested. Examples are the development of subjective probability by de Finetti and Savage (e.g., references [4] and [5]) and the so-called logical probability of Carnap [6]. The former is the concept of probability used in Bayesian inference and the latter is concerned with objective assessment of the degree to which evidence supports a hypothesis. A detailed comparative discussion of the

principal theories that have been proposed is given in Fine [7].

The emergence of probability theory as a scientific discipline dates from around 1650.

The Literature

Systematic accounts of probability theory have been provided in book form by many authors. These are necessarily at two distinct levels since a complete treatment of the subject has a measure-theory prerequisite. Elementary discussions, not requiring measure theory, are given for example, in Chung [8], Feller [9], Gnedenko [10], and Parzen [11]. A full treatment can be found in Billingsley [12], Breiman [13], Chow and Teicher [14], Chung [15], Feller [16], Hennequin and Tortrat [17], Loève [18], and Rényi [19].

Significance Level

The customary (“classical”) meaning of *significance level* (also called the α level or the *probability* of a type I error) is a property of a statistical test procedure – namely, the probability of rejecting the hypothesis tested when it is, in fact, valid (*see Hypothesis Testing; Power*). Most standard tests are constructed to control the level of significance at a prespecified value, commonly 0.01 or 0.05 (1% or 5%). Statistically significant results are sometimes reported in the scientific literature by adding a star (*) to the effect.

More recently (see, e.g. Gibbons and Pratt [1]), the term *level of significance* of a test has been applied to *data*, being the least numerical level of

significance at which the hypothesis tested would be rejected by the test if applied to the data. This is also called the *P value* (*see P Values*) for the data. Note that the lower the level of significance, in this sense, the more “highly significant” of departure from the hypothesis – in conventional phraseology – is the result of the test.

The distinction between *significance* – which relates to evidence of departure – and *importance* or *relevance* – which relates to the size and nature of the departure – is widely emphasized but often forgotten.

Overview of Statistics

Introduction

The term statistics is used in different ways. “Accident statistics” or “sales statistics” refer to numerical data in these areas. (The corresponding theoretical terminology defines statistics to be any functions of observable random variables.) Common problems encountered in the work with such data and those collected by scientists, engineers, government officials, lawyers, doctors, and so on have led to the development of general methods and principles concerning the collection, presentation, and analysis of data. The term statistics also denotes the discipline concerned with such methods.

This article considers statistics broadly as the field comprising all of the above concerns. It might be described as the enterprise dealing with the collection of data sets, and extraction and presentation of the information they contain.

New methods and formulations are constantly being developed, and new types of application come into view and in turn give rise to new problems. This flow of research is disseminated through a multitude of journals being published around the world. A listing of annual contributions is available in the *Current Index to Statistics: Applications, Methods, and Theory*, published since 1975. Much of the material prior to 1970 is listed in the five-volume *Index to Statistics and Probability* (Ross and Tukey, eds. R and D Press).

What establishes statistics as a discipline is that the same kind of data requiring the same kind of concepts and methods turn up in many different fields. On the other hand, special areas of application also may require some specialization and adaptation to particular needs. The *Encyclopedia of Statistics* gives a comprehensive overview in nine volumes and a number of updates.

Data Interpretation

Statistical Methodology

It is a central fact, underlying essentially all statistical thinking, that an actual data set typically is only one of many possible such sets that might have

been obtained under the given circumstances. (For a possible exception, see Diaconis [1].) Measurements vary when they are repeated. A store inventory, besides depending on the day on which it is taken, will be affected by bookkeeping and counting errors. In a survey, data will be obtained from different households if a new sample is to be drawn; even if the same households are visited on another occasion, different members may be at home and provide different answers; and, finally, even the same family member may answer the same questions differently on another day. As a consequence, interpretation of a data set depends not only on the actual data, but also on what (if anything) is assumed about the possible alternative observations that might have been obtained instead. The following sections consider three categories of such assumptions, and briefly indicate the kinds of statistical procedures that can be based on each.

Data Analysis

It is rare that a data set is studied without any preconceived notions. Consider, however, the idealized approach of pure data analysis in which the data are considered on their own terms. The statistical methods developed on this basis have as their primary aim (a) exploration of the data to uncover the features of principal interest and (b) presentation of the data in a manner that will bring out and highlight these features. The set of techniques dealing with (a) and (b) are called *exploratory data analysis* (see **Exploratory Data Analysis**) and *descriptive statistics* (see **Descriptive Statistics**), respectively. Both employ a great variety of numerical and *graphical* (see **Graphical Representation of Data**) techniques.

The simplest, most basic data-analytic methods concern a single batch of numbers, for example, the first-year sales of 12 novels of a successful author, 40 measurements of corrosion taken at different locations on a copper plate, or the ages of 350 000 cancer patients listed in a tumor registry. Histograms, stem and leaf displays, and one-dimensional scatter plots (see **Graphical Representation of Data**) are some of the many ways of presenting the numbers of a batch. From these one can get an impression of where the data are centered (the general level of their values), and how spread out they are. Observations that

lie far from the bulk of the data, the so-called *outliers* (see **Outliers**), may correspond to errors or exceptional cases and may deserve special attention. The display may exhibit unusual features such as bimodality, suggesting perhaps the possibility of a mixture of two batches, each unimodal but with different *modes*. If there is marked asymmetry, the possibility of making a transformation (see **Box and Cox Transformation**) (such as taking logarithms) to obtain a more symmetric data set arises.

Instead of a fairly detailed display of the data, authors frequently present only one or two summary statistics; for example, the mean or median to indicate the general level of the numbers (see **Measures of Location**), and a measure of their variability, such as the standard deviation (SD), median absolute deviation, or interquartile range (see **Measures of Scale**). A compromise is the *five-number summary*, consisting of the smallest, largest, and median observation, and the first and third *quartiles* (see **Quartiles**). These may be displayed graphically as a box plot (see **Graphical Representation of Data**).

Additional information concerning the numbers of a batch may be available and are important. If the order in which the 12 novels appeared is known, the data may show that the sales steadily increased, or that they increased up to a certain point and then leveled off, and so on, thus providing an indication of the author's changing reputation and success.

Example 1: Corrosion Data The exploratory use to which even very simple data can be put is illustrated by 40 corrosion readings taken at random over a metal plate (Campbell [2], Wolfowitz [3]). No particular pattern emerged when the observations were plotted according to their position on the plate. However, when they were plotted in the order in which they were taken, a bunching together in *runs* (see **Runs, Runs Tests**) of high and low observations suggested (as it turned out, correctly) a malfunctioning of the delicate measuring device.

Much of data analysis deals with batches of more complex units, such as pairs of numbers, more general vectors, matrices, or curves, and it need not be restricted to a single batch. With multivariate data, one may be interested in the separate features of the different variables, in relationships among the variables or sets of variables, or in aspects of the

overall pattern of the multidimensional data set. The development of graphical (including, in particular, computer-displayed) and numerical methods for these purposes is a very active area of statistical research (see **Multivariate Analysis**). It includes, among others, approaches such as cluster analysis, and multivariate classification, multidimensional scaling, pattern recognition, and factor analysis. When several batches are being considered simultaneously, comparisons of the batches will tend to be of primary interest. Given today's large volumes of data collected from industrial processes, much recent research focuses on the adoption of multivariate techniques for studying high-dimensional process data (see [4] and [5]).

Statistical Analysis Based on Probability Models

The data-analytic approach indicated in the preceding section can provide clarification of the phenomena represented by both simple and very complex data sets, and can lead to important new insights and hypotheses. In its simplest forms such as numerical summaries and histograms, it is the statistical presentation that is most frequently encountered by the general public in newspaper articles and magazine reports. (Through misleading use, it also lends itself to much mischief. See for example, Huff [6].) However, this approach lacks an often essential requirement of the resulting inferences: because of the fact mentioned earlier, that the same phenomena might have led to different observations, it is impossible to assess the reliability of the conclusions.

Such an assessment requires knowledge concerning the alternative data sets that might have been observed in the given situation, instead of the set that was observed. The crucial step underlying modern theories of statistical inference and decision making is to consider the observed data as realizations of random variables. The possible values of these variables are governed by probability distributions specifying the probabilities of observing the various possible data sets. These distributions are not assumed to be known, but only to belong to a postulated family of possible distributions. The lack of complete specification represents the unknown aspect of the situation for the clarification of which the data were collected.

For a single batch $X_1, \dots, X_n$, for example, a set of n measurements of some quantity, investigators often assume that the n observations are independent,

and that each has the same probability distribution. If this common distribution is denoted by F , the model is completed by specifying a family $\mathbb{F}$ to which F is assumed to belong. This may for example be the family of all possible distributions F (i.e., no further assumptions are made) or the family of all distributions that are symmetric with respect to a specified point of symmetry. Such broad families are called *nonparametric* in distinction to parametric families where F is known except for the values of some parameters, for example, the family of all normal, Poisson, or Weibull distributions (see **Probability Density Functions**). Once the model is specified, one can now ask, and answer, the type of question concerning a single batch considered in the preceding section, with more precision. In particular, the conclusions no longer refer to this particular data set, but to the underlying process that produced it.

Suppose for example that the aspect of interest is the overall level previously represented by the average of the observations. Suppose that $\mathbb{F}$ is the family of normal distributions with mean ξ and unit variance. Then ξ is the average value, not of these particular n measurements but rather of all potential measurements, each weighted according to its probability. The average $\bar{X} = (X_1 + \cdots + X_n)/n$, which was a descriptive measure of the general level of the batch earlier, now becomes an estimator of the unknown ξ : for example, the true value of the quantity being measured or the average value of the characteristic (e.g., height, age, or income) in the population from which the X 's were obtained as a sample.

The model assumptions make it possible to get an idea of the accuracy of an estimator such as $\bar{X}$, for example in terms of the expected closeness to the true value ξ . One commonly used measure of this closeness is the expected squared error, which for the case of n independent measurements with variance 1 equals

$$E(\bar{X} - \xi)^2 = \frac{1}{n} \quad (1)$$

This formula shows for instance how the accuracy improves with n , and enables one to determine the **sample size** n required to achieve a given accuracy.

This approach also provides a basis for comparing the accuracy of competing estimators. For the median $\tilde{X}$ of the X 's for example, one finds that approximately (if n is not too small) $E(\tilde{X} - \xi)^2 = 1.57/n$ – more than 50% larger than the corresponding value

$1/n$ for $\bar{X}$. The median is thus considerably less accurate than the mean. This conclusion depends strongly on the assumption that the X 's are normally distributed. For other distributions the result may be just the reverse (see **Estimation**).

Another way of describing the accuracy of $\bar{X}$ is obtained by noting that

$$P\left[|\bar{X} - \xi| \leq \frac{1.96}{\sqrt{n}}\right] = 0.95 \quad (2)$$

so that with probability 0.95 the estimator $\bar{X}$ will differ from the true value ξ by less than $1.96/\sqrt{n}$. The statement (1) can be paraphrased by saying that the random interval $(\bar{X} - 1.96/\sqrt{n}, \bar{X} + 1.96/\sqrt{n})$ will contain the unknown ξ with probability 0.95. Random intervals that cover an unknown parameter ξ with probability greater than or equal to some prescribed value γ are called *confidence intervals* (see **Confidence Intervals**) at confidence level γ .

Point **estimation** and estimation by confidence intervals provide two of the classical approaches to statistical inference. The third is *hypothesis testing* (see **Hypothesis Testing**).

Example 2: Extrasensory Perception Suppose the claim of a subject A to have extrasensory perception (ESP) is to be tested by tossing a coin 100 times at a location invisible to A, and recording A's perception (heads or tails) for each toss. Suppose that A obtains the correct result on 54 of the tosses. This clearly is not an indication of a strong ability at ESP. However, even a very slight ability would be of extraordinary interest. Is there support for such a finding, or is the result compatible with purely random guessing? Under the null hypothesis of pure guessing, the probability of calling a toss correctly is $1/2$ for each toss, and the probability of getting 54 or more right is then $1/4$. The result is therefore not particularly surprising under H , and a case for A's ability to do better than chance has not been made. Had A correctly identified 65 tosses rather than 54, the conclusion would have been quite different. The probability of 65 or more correct calls is only 0.002 when H is true. In the light of so extreme a result, one would have to give serious attention to A's claim.

Hypothesis testing, and point and interval estimation are all used extensively in applications, with each being more useful and popular in some areas than in others. The theory of these three methodologies

is concerned with the performance of proposed procedures (including the determination of sample size to achieve a desired performance), the comparison of different procedures, and the determination of optimal ones. An important consideration is the robustness of a given procedure under violation of the model assumptions. If the procedures are very sensitive to these assumptions, one may want to study the problem in a nonparametric setting of the kind described for a single batch at the beginning of this subsection. Nonparametric (and semiparametric) models are particularly important for the analysis of large data sets, which has become more practicable as a result of increased computer capabilities and availability.

A unified framework for the three areas is provided by Wald's decision theory. This very general theoretical approach deals with the choice of one of a set of possible decisions d on the basis of observations x_i . Let the chosen d be denoted by $\delta(\mathbf{x})$. The observed value $\mathbf{x}$ is assumed to be the realization of a random quantity $\mathbf{X}$ with probability density $p_\theta(\mathbf{x})$, θ unknown. A loss function $L(\theta, d)$ measures the loss resulting from decision d when θ is the true parameter value, and the performance of a decision procedure δ is measured by its *risk function*

$$R(\theta, \delta) = E_\theta [L(\theta, \delta(\mathbf{X}))] \quad (3)$$

that is, the average loss incurred by δ when θ is true. A principal concern of the theory is the determination of a δ for which the risk function is as small as possible in some suitable sense. Another problem is the characterization of all admissible procedures, i.e., all procedures whose risk cannot be uniformly improved.

Decision theory can also be made to encompass sequential analysis, the **design of experiments** (by letting the loss function take account of the cost of observations), and the choice of model (by imposing a penalty that increases with the complexity of the model). However, it is an abstract approach that has been useful primarily for exhibiting general relationships rather than for its impact on specific methods. An important consequence of Wald's theory has been its liberating effect on the formal consideration of new types of situations, among them multiple comparisons and other simultaneous inference procedures.

Exploration versus Verification

To illustrate both the relation and the difference between the approaches described in the preceding two sections, consider once more the ESP example.

Example 2: Extrasensory Perception (Continued)

When looking at the results of the 100 tosses, suppose the experimenter notices that of the 54 successes, 33 occurred during the last and only 21 during the first 50 tosses. The probability of 33 or more successes in 50 tosses with success probability $p = 1/2$ is only about 0.01. One might be tempted to explain away the poor performance in the first half of the experiment by the theory that it requires some warming up before the ability hits its stride, and to declare the success of the second half significant. However, such a conclusion would not be justified on the basis of this analysis since the calculation does not take account of the fact that the particular test (restricting oneself to the second half) was not originally planned but was suggested by the data.

Suppose that the situation had been reversed, that there had been 33 successes in the first and 21 in the second half. A possible explanation is that the exercise of ESP requires great concentration, and after 50 attempts the subject is likely to get tired. Similar explanations could have been found if success had been unusually high in the middle 50, or on the last 25, or the first 25, and so on. Instead of high concentration of successes in a particular segment of the sequence, other patterns might have struck an observer: for example, a gradual rise in the frequency of success, or a cyclic pattern of successes and failures, and so on. For each, an explanation could have been found.

This is the problem of *multiplicity*. Every set of observations – even a completely random one – will show some special features, and explanations can usually be found *post facto* to account for them. Unfettered examination of many different aspects of a data set is legitimate, and in fact a primary purpose, of exploratory data analysis. However, the results will then tend to look more impressive than they really are since attention is likely to focus on the extremes of a large number of possibilities. To legitimize a theory suggested by the data, one must test it, for example, on a separate part of the data not used at the exploratory stage or from new data specially obtained for this purpose. (A

somewhat more limiting alternative to such a two-stage procedure is to formulate a number of possible theories to be considered before any observations are taken. The simultaneous testing of such a number of possibilities provides a legitimate calculation for the probability of the most striking of the associated results.)

The two stages, exploration of the data leading to the formulation of a hypothesis, followed by an independent test of this hypothesis, constitute the basic pattern of scientific progress as described by scientists (see for example, Feynman [7, Chapter 7]) and discussed by philosophers of science. Before considering a third aspect in the next section, let us briefly mention another distinction, which relates to the purpose of a statistical investigation. This is the difference between inference and decision making. It may be illustrated by the problem faced by a doctor who wants to arrive at a diagnosis (inference) but must also select a treatment (decision).

Example 3: Medical Diagnosis Suppose there are k possible conditions (diagnoses) $\theta_1, \dots, \theta_k$ that might have led to the observed symptoms and test results $\mathbf{X}$ (the data), including for example measurements of temperature, blood pressure, and so on. Under condition θ , the observations $\mathbf{X}$ have a distribution $p_\theta(\mathbf{x})$. The problem of diagnosis is thus the statistical problem of using the observed value of x to determine the correct value of θ . (A standard procedure is to select the value $\hat{\theta}$ of θ that maximizes $p_\theta(\mathbf{x})$ for the given observation $\mathbf{x}$, the so-called maximum-likelihood estimate (see **Maximum Likelihood**) of θ .) The associated decision procedure might be to select the treatment that would be most appropriate for the chosen θ . The situation is however more complicated since the choice of treatment must also take account of the severity of the consequences in case of an incorrect diagnosis resulting in a nonoptimal treatment, the so-called loss function. The distinction between inference and decision making is reviewed in Barnett [8]. For a discussion of computer-based medical diagnosis and treatment choice, see Shortliffe [9] and Spiegelhalter and Knill-Jones [10].

Bayesian Inference and Decision Making

Example 3: Medical Diagnosis (Continued) Suppose a patient P being tested for the conditions

$\theta_1, \dots, \theta_k$ of the last example is told that the tests point to $\hat{\theta} (= \theta_1, \text{ say})$ as the most likely cause of the symptoms. Naturally, P wants to know just how likely it is that θ_1 is in fact the true cause. The doctor has to admit that the term *most likely* was used imprecisely; that $\hat{\theta} = \theta_1$ is the condition that assigns the highest probability to the observed test results, not necessarily the most likely of the conditions $\theta_1, \dots, \theta_k$, and that in fact no probability can be assigned to these conditions.

Actually, in this example it may be possible to make such an assignment. Suppose that π_i is the incidence of condition θ_i in the population of sufferers from the given symptoms, and hence is the probability that a patient drawn at random from the population of such sufferers has condition θ_i . The condition of such a patient is then a random variable Θ , with prior probability $P(\Theta = \theta_i) = \pi_i$ before the tests are taken, and posterior probability $P(\Theta = \theta_i | \mathbf{x})$ in the light of the test results $\mathbf{x}$. The latter probability can be calculated from the π_i and the $p_{\theta_i}(\mathbf{x})$ by Bayes' theorem.

On being presented with this probability, P may however still not be satisfied but complain to the doctor: "You have treated me for 20 years, you know my complete medical history, lifestyle, and habits. In the light of all this additional information, what is the probability of suffering from θ_i not for a random patient but for me personally?" Unfortunately, the interpretation of probability as frequency, which was tacitly assumed up to now, and which in particular applied to the prior probabilities π_i of the preceding paragraph, precludes assigning probabilities (other than 0 or 1) to unique events such as this particular patient's suffering from condition θ_i .

This difficulty is met head-on by the Bayesian approach according to which π_i can be chosen to represent the physician's probability that condition θ_i obtains for this particular patient. This meaning of probability is, however, different from the earlier one. Probability is no longer a frequency but the degree of belief attached to the event in question. (If the event is repetitive, this probability typically draws close to the observed frequency as the number of cases gets large.)

In general, the Bayesian approach assigns a *prior probability distribution* to a parameter θ before the observations $\mathbf{X}$ are taken. Once the values $\mathbf{x}$ of $\mathbf{X}$ are available, the prior distribution of θ is updated to

the posterior (i.e., conditional) distribution of θ given $\mathbf{X} = \mathbf{x}$, which shows how the prior beliefs regarding the chances of different θ values have changed in the light of the data.

In the decision theoretic terminology introduced earlier, the relevant assessment of the performance of a procedure δ from a Bayesian point of view is not the risk function $R(\Theta, \delta)$ but rather the posterior expected loss

$$r(\mathbf{x}, \delta) = E [L(\theta, \delta(\mathbf{x})|\mathbf{x})] \quad (4)$$

calculated according to the conditional distribution of θ given $\mathbf{x}$.

Ideally a Bayesian has a comprehensive, consistent view of the world with a probability attached to every unknown fact. These probabilities must satisfy an appealing set of axioms (the axioms of *coherence*), and must be updated as new information becomes available. For an individual's response to the world (or even a specific problem), a chief difficulty in implementing this program is the determination of the prior distribution. A considerable literature deals with methods for eliciting a person's degrees of belief with respect to a given situation, but there is also an *objective Bayesian school* in which the prior distribution represents "total lack of information".

Ideally, each person has a single correct personal probability regarding any unknown event. However, in practice, these probabilities "can never be quantified or elicited exactly (i.e., without error) especially in a finite amount of time" (Berger [11, p. 64]). This has led to the suggestion of a robust Bayesian viewpoint according to which one "should strive for Bayesian behavior which is satisfactory for all **prior distributions** which remain plausible after the prior elicitation process has been terminated" (Berger [11]).

A second difficulty arises in situations in which the decision or opinion concerns not a single person, but represents a joint problem for a group or occurs in the public domain, as for example in the publication of the analysis of a scientific investigation. Some aspects of this problem will be considered in the next section.

The Bayesian/Frequentist Controversy

The mutual criticism of Bayesians and frequentists has given rise to a lively (and sometimes acrimonious) debate, which has helped to clarify a number

of basic statistical issues. (There are many different variants of Bayesians and frequentists, not all of which will agree with the positions ascribed to these approaches here.) One of the central concerns is that of subjective *versus* objective data evaluation in scientific inference and reporting. Fisher, Neyman, and Pearson developed their frequentist theories in a deliberate effort to free statistics from the Bayesian dependence on a prior distribution, and this aspect has continued as the central frequentist objection. The Bayesian response to this criticism is twofold. On the one hand, it is pointed out that frequentist analysis involves similar types of specification. There is the choice of model and loss function, both of which must be chosen in the light of previous experience and involve judgments that are likely to vary from one person to another. In addition, there is the problem of selecting a frame of reference that forms the basis of the frequency calculations. In assessing the incidence of the conditions $\theta_1, \dots, \theta_k$ of the preceding section, for example, for what population should this be calculated: the population of the world, or the country, or the city in which the person lives; should the comparison be restricted to patients of the same age, sex, and so on? This is the problem of conditional inference, which so far has found no satisfactory frequentist solution. (For the Bayesian, the problem does not arise in this form since the probabilities will always refer to this particular patient, but the same issue arises when one must decide how to weigh the experience with other patients in forming an opinion about this one.)

As a more positive response, there have been Bayesian suggestions (for example, Dickey [12], Smith [13]), that in scientific inference the analysis should be reported under a variety of different priors that – it is hoped – will include the opinions of the readers. The view that "any approach to scientific inference which seeks to legitimize *an* answer to complex uncertainty is a totalitarian parody of a would-be rational human learning process" (Smith [13]) considerably narrows the gulf between the two approaches.

The reason for this narrowing can be found in the combination of two facts. The first is a basic result of Wald's (frequentist) decision theory to the effect that every admissible procedure is a Bayes solution or a limit of Bayes solutions. Secondly, frequentists tend not to believe in a unique correct approach, and may

therefore try a number of different solutions corresponding to different optimality principles, robustness properties, and so on. If these lead to similar conclusions, any one of them can be adopted. Otherwise, a careful examination of the differences may clarify the reason for the discrepancies and point to one as the most appropriate. Lacking such a resolution, one may instead prefer to report a number of different procedures.

The Bayesian and frequency approaches lead to different ways of assessing the performance of a decision procedure. From a strict Bayesian point of view, only the posterior distribution of θ given $\mathbf{x}$, and the posterior expected loss $r(\mathbf{x}, \delta)$, are relevant, while frequentists measure the performance of a procedure by its risk function. However, on this issue also, an accommodation to statistical practice and the need for communication has narrowed the gap by generating a Bayesian interest in risk functions. Thus Rubin [14, p. 116] writes, “Frequency calculations that investigate the operating characteristic of Bayesian procedures are relevant and justifiable for a Bayesian when investigating or recommending procedures for general consumption.” Similar considerations can be found in Berger [15].

In the other direction, the frequentist approach has been strongly influenced by Bayesian ideas, in particular, by recognizing that it is natural and useful to consider the prior distribution leading to a proposed admissible procedure. An example in which such a Bayesian interpretation has made an important contribution to a theory developed in a decision theoretic framework is that of Stein estimation.

Data Acquisition

Measuring Single Units

The first part of this entry dealt with the interpretation of data once they have been collected. In this and the following sections, we consider some of the processes that produce data, and the statistical problems arising at this earlier stage. (An extensive discussion of various types of data is provided in Hoaglin *et al.* [16].)

The basic data units are the numbers, symbols, words, or other entries making up a data set; for example, measurements of the height of a person or plant, or of the weight of a wagonload of fruit or a minute amount of some chemical; barometer or

temperature readings; or the scores of a student in an intelligence or aptitude test. Alternatively, the observations could be the information provided by a person answering a questionnaire or an interviewer, such as family size, last year’s income, or religious and political affiliation.

A concern for **data quality**, for their reliability and validity, is an important task preceding the collection of data (*see Measurement Systems Analysis, Overview*). Efforts must be made to eliminate **bias**, reduce variability, and eliminate sources of error. The repeatability and reproducibility of measuring gauges should be assessed, and if needed improved. In constructing a questionnaire, great care is required to avoid ambiguities. Checks on the reliability of responses can often be built into the data set, for example by asking for the same information in a number of different ways or in different contexts.

Another aspect of data improvement arises after the data have been obtained. Data editing (or “cleaning”) involves the deletion or modification of entries that do not appear to be in consonance with the rest of the data and that sometimes represent obvious errors (for example, in a series of monthly measurements of a baby’s head circumference when one month’s measurement is smaller than the preceding ones). A variety of statistical methods have been developed for this purpose. In addition, robust statistical procedures are available that satisfactorily control the effect of outlying observations (*see for example Hoaglin et al.* [17] and Hampel [18]). On the other hand, data cleaning by inspection, without clearly stated rules, runs the risk of introducing a subjective element. (For example, just which observations are to be singled out for such treatment?) Even with good rules, it may remove valuable evidence and destroy the basis for probability calculations. For this reason, it is typically better to consider the editing of data as part of the statistical analysis and, while perhaps indicating definite or suspected errors, not to change the original data.

The improvement of data quality mentioned above is not the only aspect of **data collection** to be considered before obtaining the observations for an investigation. Two questions, in particular, that are of crucial importance and that will be discussed in the next sections are how many and what kind of observations are required.

Assessing Population Characteristics

The target of most investigations is not a single

unit but a population of such units (or the process generating the units). A set of professors, apples, days, mice, or light bulbs is typically examined not because of interest in these particular specimens but in order to reach conclusions about the populations they represent. (It is this aspect and the associated quantification that has earned statistics its reputation of being antihumanistic.)

Efforts to obtain information about every member of the target population through a census go back to at least the third millennium B.C. in Babylonia, China, and Egypt. (For a nontechnical history of the census, see Alterman [19].) The purpose was usually to provide a basis for taxation or proscription. Today, population censuses seeking a great variety of information are carried out, many of them at regular intervals, in nearly all countries of the world.

However, taking a complete inventory is not the only way to obtain accurate statistical information about a population (and in the case of an infinite population, such as the one consisting of all products that a process manufactures, it is not even possible). The same end can usually be achieved more economically by collecting information only from the members of a sample, taken from the population by a suitable sampling method. The much smaller size of the sampling operation tends to make this procedure not only cheaper but also more accurate since it permits better control of the whole process and hence the quality of the resulting data. On the other hand, a census has the advantage – not shared by any sample – of providing information even for very small subpopulations.

Suppose a population Π consists of N units, each of which has a value v of some characteristic of interest, such as the age or income in the case of a human population, the number or weight of the apples on each of the N trees in an orchard, or the length of life or brightness of the lightbulbs in a shipment received from the factory. To obtain an estimate of the average v value $\bar{v} = (v_1 + \cdots + v_N)/N$, a sample is taken from the population. In the early days of sampling, investigators usually relied on judgment samples, in which judgment is used to obtain a sample “representative” of the population. It is now realized that such sampling tends to lead to biases, and does not provide a basis for calculating accuracy or the sample size needed to achieve a desired accuracy. The methods used instead are probability **sampling schemes** that select the units to be included in the sample according to stated probabilities. The simplest

such scheme is simple random sampling, according to which n units are chosen in such a way that every possible sample of size n has the same probability of being drawn. The average of the sample v values is then the natural estimate of $\bar{v}$.

Better accuracy can often be attained, and the needed sample size and resulting cost therefore reduced, by dividing the population to be sampled into strata within which the v values are more homogeneous than in the population as a whole but which differ widely among each other. (The population of school children of a city might for example be stratified by school, grade, and gender.) A stratified sample of size n is then obtained by drawing a simple random sample of size n_i from the i th stratum for each i , where $\sum n_i = n$.

In a different direction, the cost of sampling can often be reduced by combining units into clusters (for example, all the apartments in an apartment house, all houses in a city block, or all patients in a hospital ward), and obtaining the required information for each member of a sampled cluster. The two approaches can be combined into stratified cluster sampling, and many other designs are possible.

Sample surveys to obtain information about a population are in widespread use and have become familiar through election polls, market surveys, and surveys of television viewers to establish ratings. However, they are not very well understood. In particular, it appears puzzling how it is possible to obtain an accurate estimate of the opinions or intentions of many millions from information concerning just a few thousands.

Example 4: Election Poll To get some insight into this question, let us simplify the situation, and suppose that a population Π consists of a large number N of voters, each of whom supports either candidate A or B. A simple random sample of n voters is drawn from Π , and the preference of each member of the sample is ascertained. If X is the number of voters in the sample favoring A, then X/n , the proportion of A supporters in the sample, is the natural estimate of the proportion p of A supporters in the population.

The question at issue is how large a sample is required for X/n to achieve a prescribed accuracy as an estimate of p , for example, for the standard

deviation (SD) of X/n to satisfy

$$\text{SD}\left(\frac{X}{n}\right) \leq 0.01 \quad (5)$$

It is often felt intuitively that the required sample size n should be roughly proportional to the population size N . However, it turns out that this intuition is misleading and that in fact, for large populations, the required n is essentially independent of the value of N .

To see this, suppose for a moment that the sampling is done “with replacement”, i.e., that the members are drawn successively at random, with each – after giving the required information – being put back into the population before the next member is drawn, again at random. This method is slightly less efficient than the original simple random sampling (and therefore requires a larger sample size), because it allows the same unit to be drawn more than once. It is introduced here because it is particularly simple to analyze. Sampling with replacement is characterized by two properties: (a) on each draw, the probability of obtaining an A supporter is p ; (b) the results of the n draws are independent in the sense that the probability of getting an A supporter on any given draw does not depend on the results of the earlier draws.

Let us now compare this situation with a quite different one. Suppose a coin with a probability p of falling heads when spun on its edge (this probability may be far from $1/2$), is spun n times and that X is the number of times it falls heads. Then (a) the probability of heads is p on each spin, and (b) the results of the n spins are independent. The standard deviation of X/n is therefore the same for this coin problem as in the election sampling with replacement. The number n required to reduce this standard deviation to 0.01 is therefore also the same in both cases. Note however that the coin problem involves only n and p ; no population is involved. Therefore the required n cannot depend on N .

This argument depends of course crucially on the assumption that the sampling was random. It is the randomness that insures that with high probability the sample contains approximately the same proportion of A supporters as the population. In addition, it was tacitly assumed that the preference of each voter can be ascertained without error. In practice, the possibility of “response error” can rarely be ruled out.

Data from Experiments

A study is called an *experiment* if its data are produced by an intervention (i.e., do not occur naturally) for the purpose of gathering information. It is a *comparative experiment* if its purpose is to compare several ways of doing something (e.g., different machines, procedures, medical treatments, fertilizers, and so on) rather than to determine some absolute value.

Example 5: Weather Modification Consider a company’s claim to be able to increase precipitation by seeding the clouds of suitable storms. Here the comparison is between seeding and not seeding. How can one obtain data to test the claim and to provide an estimate of the amount of increase?

As one possibility, the company might seed all suitable storms in the given location, and compare the resulting rainfall with that during the corresponding period in the preceding years. Of course, if the results are very striking (for example, if an enormous downpour occurs immediately following each seeding) this may settle the issue. However, typically the results are less clear. Suppose, for example, that the total rainfall matches, or even slightly exceeds, that of the wettest of the last five years. This may be the result of the seeding; or it may just be the consequence of an exceptionally wet year.

This difficulty is inherent in studies in which there is no randomness in the assignment to the experimental units of the conditions or treatments being compared. A better basis for the establishment of a causal relationship – in this case that the increased rainfall is due to the seeding – is obtained if storms are compared within the same season, and if they are assigned to the two treatments (seeding and not seeding) according to a random mechanism. This can be done in a variety of ways, corresponding to different experimental designs.

As a simple possibility, suppose that the experiment is to extend to the first 20 storms that are suitable for seeding. Of these, 10 will be seeded and 10 not, the latter providing the *controls*. According to one design (**complete randomization**), 10 of the numbers $1, \dots, 20$ are selected at random; the storms bearing these numbers will be seeded, the remaining 10 will not. An alternative design (*paired comparisons*) pairs the storms $(1, 2), (3, 4), \dots, (19, 20)$, and within each pair assigns at random (e.g., by

tossing a coin) one storm to seeding, the other to control. This second design will be particularly effective if storms occurring close together in time are more likely to be similar in strength than storms separated by longer intervals.

It is interesting to note the close relationship of these designs to the sampling schemes of the preceding section. In the first design, the storms assigned to seeding are a simple random sample of the 20 available storms; in the second case, they constitute a stratified sample, with samples of size 1 from each of 10 strata of size 2.

Unfortunately, random assignment of the conditions being compared is not always possible. Consider for example a study that reports that married men tend to live longer than unmarried ones. It is tempting to draw the conclusion that marriage prolongs life, perhaps by providing a more regulated lifestyle. However, such a conclusion is not justified. Married and unmarried men constitute groups that differ in many ways. The latter for instance includes men with health problems that preclude marriage and that also tend to shorten life. It is thus not clear whether the observed effect is the result of the difference in marital status or of conditions leading to this difference. All that can be safely concluded is that marriage is associated with longer life expectancy. This may be enough for an insurance company but does not answer the sociological or public health question regarding the effect of marriage. Quite generally, *observational studies* (see **Observational Studies**) in which subjects have not been assigned to the conditions being compared (marital status, smoking habits, religious beliefs, and so on) can establish associations (such as that between marital status and longevity) but have great difficulty in validating causal relationships. To establish *causation* (see **Causality**) is a cherished goal of statistical methodology but tends to be rather elusive. (For some further discussion of this point, see for example Mosteller and Tukey [20, pp. 260–261] and Holland [21].)

Example 6: Headache Remedy Suppose that you wake up with a headache, take a headache remedy, and an hour later find that the pain is gone. On the basis of this isolated instance (which, in words attributed to R. A. Fisher, is an experience rather than an experiment), it is clearly not possible to conclude that the result is due to the remedy. The cause might instead have been another intervening event such as

breakfast, or possibly the headache had run its course and would have dissipated in any case.

The attribution of the cure to the medication becomes much stronger if the incident is not isolated. If you have suffered from headaches before, took the medicine sometimes soon after onset, at other times only after having waited in vain for the pain to subside on its own; if on different occasions you took the tablets at different times of day, and if under all these different circumstances the headache disappeared shortly after treatment and never (or only very rarely) before, the robustness of the effect over many different conditions would tend to carry conviction where a single instance would not. The finding could be strengthened further if your own experience could be merged with that of others. (However, even if the evidence for a treatment effect is convincing, observations of this kind cannot determine whether the ingredients of the medication are responsible for the improvement, or whether it is a *placebo effect*, i.e. the patient's belief in the effectiveness of the treatment, which relieves the pain.)

To see how to systematize the informal reasoning of the preceding paragraph, consider another example.

Example 7: New Traffic Signs Suppose that four-way stop signs have been installed at a dangerous intersection, and that four accidents had occurred in the month preceding the installment of the signs but only one in the month following it. These facts by themselves provide little basis for an inference. Suppose for example that the monthly accidental frequencies constitute a purely random sequence of which the value 4 was by chance high, which however caused the installment of the signs. Then even without this intervention, a decrease could have been expected in the succeeding month.

A more meaningful comparison can be obtained if the accident statistics are available not only for one month before and after, but for several months in both directions. One is then dealing with an interrupted times series, for which it is possible to compare the observations before with those after the “interruption” (the installment of the signs). Even the nonrandom choice of the time of intervention would then have only a relatively minor effect.

While the interrupted **time series** can establish that the accident rate is lower after installment than

it was before, it cannot establish the new signs as the cause of the decrease since other changes might have occurred at the same time. To mention only one possibility, the community may have been affected by editorials published at the time of the third and fourth accidents. Some control – although not as firm as that resulting from randomization – can be obtained by studying the accident rates during the same months at some other intersections also, a multiple time series design. If the other series do not show a corresponding decrease, this will clearly strengthen the causal argument.

Quasi-experiments (a better term might be “quasi-controlled experiments”) such as the interrupted time series and multiple time series described above, which try to identify and control the most plausible alternatives to the treatment being the cause of the change, are treated by Cook and Campbell [22] and Cochran [23] (for an elementary discussion see Campbell [24]). They can greatly strengthen the causal attribution although they cannot be expected to be as convincing as a controlled randomized experiment.

Serial Data

Most of the data considered so far were assumed to be collected on a one-shot basis. Often, they are obtained instead consecutively over a period of time. Such data are particularly useful in assessing changes over time. (Are winters getting colder? Is the birth rate in the United States falling? Is a process producing products of stable quality?)

An important application is provided by statistical **quality control**. An established production process is monitored by taking observations of the quality of the product at regular intervals. The process is said to be in control if the successive observations are independent and have the same distribution. A *control chart* (see **Control Charts, Overview**) on which the successive observations are plotted provides signals when the process appears to be going out of control. A similar approach is used in monitoring the cardiogram of a heart patient in **intensive care**, where the data consist of a continuous graph instead of a discrete sequence of points. Analogously, seismographs provide continuous data for the monitoring of seismic activity while persons watching their weight through regular weighings provide another illustration of the discrete case.

In these applications, a single process is followed to check that no changes are occurring and to alert us when they occur. A different situation arises when one is interested in assessing the changes occurring in a population as part of a developing pattern or as the result of some intervention. For example, to study the dynamic behavior of a chemical process, or stock prices, one collects a sequence of observations. To study the pattern of growth (the *growth curve*) of children, plants, or institutions, one observes each member of a sample from the population over a period of time. In such time series data and *longitudinal studies* the observations at different times often are dependent. Probability models for sequences of dependent observations are considerably more complicated than those for sequences of independent and identically distributed (i.i.d.) variables. Such models and their statistical analysis are treated in the theory of *time series* (see **Time Series Analysis**) or more generally of stochastic processes.

Observations arising serially, for instance on patients coming to a clinic, successive books by an author, or stock market performance in successive time periods, provide an opportunity to economize by letting the size of the study be determined by the data (according to a clearly specified rule) instead of fixing it in advance. Suppose for example that a shipment of goods is being sampled to determine whether its overall quality meets certain specifications. Items are being drawn at random and examined one by one. It may then be possible to stop early when the quality of the initial observations is either very satisfactory or very unsatisfactory, while one may wish to take a larger sample when the initial observations are mixed. The working out of economical stopping rules providing the desired statistical information, and the analysis of the resulting data, is the problem treated in *sequential analysis*.

Designing Experiments

The first part of this article was concerned with the interpretation of data once they have been obtained, and the preceding sections with various processes used to acquire the data. However, preceding even this stage, it is necessary to plan how many and what kind of data will be needed to answer the questions under consideration.

As an illustration, consider once more the ESP study of Example 2, based on 100 tosses of a coin. Suppose the investigator had decided, before the experiment was carried out, to give serious attention to the possibility of ESP, provided the number of subject A's correct calls would be at least 65. As pointed out in Example 2, under the hypothesis of pure guessing, the probability of 65 or more answers is 0.002. There is thus little danger of paying attention to the claim if it has no validity.

However, is this study giving subject A a fair shake? What is the probability of getting 65 or more of the tosses right if A really does possess the claimed ability? The answer depends of course on the extent of the ability, which can be measured by the probability of calling a toss correctly. Here are some values, computed under the simplifying assumptions that the 100 calls are independent, and that the probability p of a correct call is the same for each toss.

p	0.55	0.6	0.7	0.75
$P(\text{number of correct calls} \geq 65)$				
= power	0.027	0.179	0.884	0.990

The probability in this table measures the **power** (see **Power**) of the test of the hypothesis $H : p = 1/2$, i.e., the probability of following up A's claim against various alternative values of p . It shows that the power is quite satisfactory when p is 0.7 or more, but not, for example, when $p = 0.6$. In this case, despite the large discrepancy between pure guessing and an ability corresponding to $p = 0.6$, the probability is less than 20% that serious attention would be given to the claim. To get higher power would require a larger number of tosses. For example, to increase the power against $p = 0.6$ to 0.9, while keeping the probability of following up the claim when $p = 0.5$ at 0.002, would require a sample of about 425 tosses instead of the previous 100. A statement of the goals to be achieved, e.g., the required power of a test or accuracy of an estimate, and determination of the sample size needed for this purpose, are crucial aspects of planning a study.

Taking a fixed number of observations (100 or 425, etc.) is not necessarily the best design. Suppose for example that A calls all of the first 25 tosses correctly. This may be enough to provide the desired evidence of A's ability (or suggest that something is wrong with the experiment). Thus, a sequential

stopping rule of the type indicated at the end of the previous section might be more efficient.

Consider next the problem of determining an **optimal design** when different types of observations are involved. Suppose that we are concerned with the comparison of two treatments, and that the total number of observations is fixed at $N = 2k$. Then it will typically be best to assign k subjects to each treatment, since this will tend to maximize the power of the tests and minimize the variance of the estimate of the difference. This may of course not be the case if observations on one of the treatments have smaller variance than on the other.

Finding the optimum assignment becomes much more difficult when observations are taken sequentially, and a decision is required at each stage as to which treatment to apply next. What is the best (or even a good) rule depends strongly on the purpose of the procedure. If the only concern is to decide whether the treatments are equally effective and, if not, which is better and by how much, the treatments should be assigned in a balanced way, i.e., so that each is received by the same number of subjects. However, if one is comparing two treatments of a serious medical condition, an additional consideration arises: a desire to minimize the number of patients in the study who receive the inferior treatment. A sequential procedure that has been suggested for such a case is the "play the winner rule" in which the next patient receives the treatment that at that point looks better. (For details, see for example, Flehinger and Louis [25] and Siegmund [26].) It should be noted however, that such an unbalanced procedure will require more observations than the best balanced rule, and hence will take longer to lead to termination of the study and hence to a recommendation. Thus, the inferior treatment will be assigned to fewer patients within the experimental group but to a larger number outside of it.

Comparative experiments typically involve more than the study of just one difference. Consider an experiment to investigate the effect of a number of factors (to which experimental units can be assigned at random) on some observable response such as rainfall, crop yield, or length of life. Two possible designs are one-at-a-time experiments, in which each factor is studied in a separate experiment with all other factors held constant, and *factorial experiments* (see **Factorial Experiments**), which provide a joint

study of the effects of all factors simultaneously. The latter type of design has two important advantages.

Two or more effects may interact in the sense that the effect of one factor depends on the level of the other. In a study of the effect of textbooks and instructors on the performance of students, for example, it may turn out that a textbook that works very well for one instructor is quite uncongenial to another. The existence and size of such interactions are most easily investigated by studying the various factors simultaneously. When no interactions are present, joint experimentation has the advantage of requiring far fewer observations to estimate or test the various effects than would be needed if each factor were studied separately. (For further discussion of these and related issues see for example, Cox [27] and Box *et al.* [28].)

Much of the theory of factorial designs was originated by R. A. Fisher in the 1920s, in the context of agricultural field trials, where it continues to play a central role; in addition, its uses have since expanded to many other areas of application. The paper on **response surface** analysis by Box and Wilson [29] marked the starting point of their adoption in industry.

Conclusion

Statistics has been discussed in this article as dealing with the collection and interpretation of *data* to obtain information. We have been particularly concerned with the uncertainty caused by the fact that the observations might have taken on other values, and with the resulting variability of the data. An alternative view of statistics is obtained by noting that uncertainty attaches not only to data, but also to many other “chancy” events such as length of life, the occurrence of accidents, the quality of a manufactured article, or the fall of a die. Correspondingly, statistics has also been defined as the subject concerned with understanding, controlling, and reducing *uncertainty*. Actually, there is little difference between these two descriptions: data involve uncertainty, and the study of any particular uncertainty requires the collection of appropriate data. It is a matter of emphasis.

Earlier sections have given a general indication of the pervasiveness and impact of statistical considerations relating to both data and uncertainty. To illustrate the power and wide range of the statistical

Table 1 ^(a)

Vaccinated	200 745	57
Placebo	201 229	142

^(a) Adapted from Meier

approach, we shall in this concluding section take a brief look at three specific studies.

Example 8: Polio Vaccine Trial To test whether a proposed polio vaccine (the Salk vaccine) was effective, a large scale study was carried out in 1954. The most useful part of the study was a completely randomized trial in which about half of approximately 400 000 school children were assigned at random to receive the vaccine, with the other half receiving a placebo (injection of an ineffective salt solution). The study was double blind, i.e., neither the children nor the physicians making the diagnosis knew to which of the two groups any given child belonged. The results in Table 1 show that vaccination has cut the rate of polio by about 60%. The probability of that marked a decrease under the hypothesis that the vaccine has no effect is about $1/10^7$, much too small to reasonably attribute the effect to pure chance. (Note that this example is of the same type as the hypothetical Example 2 (ESP).)

Example 9: Medical Progress In the preceding example we were concerned with the effectiveness of a single medical innovation – the Salk vaccine. The study reported in the present example (Gilbert *et al.* [30]) addresses a much broader question: What can be said about the effectiveness of present-day medical (or rather more specifically, surgical and anesthetic) innovations as a whole? Such an investigation of the combined implications of a whole area of studies is called a *meta-analysis*. (For an account of meta-analysis with many references to the literature, see Hedges and Olkin [31].)

A first step toward such an analysis is to decide what data to collect, in particular, which studies to include in the investigation. Ideally, one would like to have a list of all relevant studies for the period in question. For medical research, an approximation to this ideal is available in National Library of Medicine’s MEDLARS (MEDical Literature And

Table 2 ^(a)

	Innovation highly preferred	Innovation about standard			Standard highly preferred	Total
		Preferred	Equal	Preferred		
Randomized	5	7	14	6	4	36
Nonrandomized	5	2	3	1	1	12

^(a)© WW Norton & Company, Inc, 1978

Retrieval System), which provides exhaustive coverage of the world's medical literature since 1964. From MEDLARS, the authors obtained a set of 107 papers ("the sample") evaluating the success of specific innovative surgical and anesthetic treatments, and used these to assess the effectiveness of such treatments as a whole. The authors view this set of papers as a sample from the flow of such research studies, and therefore believe that the results should give a realistic idea of what to expect from future innovations, at least for the short term.

The sample contained a total of 48 comparisons of a new treatment with a standard (control). In 36 of the cases, the assignment to treatment and control was randomized, but not in the remaining 12. The results are summarized in Table 2.

A striking feature of the results for the randomized trials is that only 5 out of 36 or about 14% of the innovations were highly preferred. This suggests, the authors point out, that medical science is sufficiently well established so that substantial improvements over the standard treatments are difficult to achieve yet that it is not so settled that only a major theoretical advance will lead to any substantial further improvements.

A more sanguine assessment is obtained from the nonrandomized studies, where 5 out of 12 or about 42% of the innovations were highly preferred. Since randomization provides a surer foundation, the results in the first row may be deemed to be more reliable than those in the second. However, such a judgment overlooks the fact that the comparison of randomized with nonrandomized studies is itself not randomized, i.e., the assignment of studies to these two types was not, and was in fact far from, random. As a result, the two types of studies may not be directly comparable. For example, a surgeon who is strongly convinced of the great superiority of the new treatment, might for ethical or other reasons not be willing to apply the standard treatment, and would therefore have to

look for controls from an earlier period or from other surgeons, while no such qualms might arise for a less dramatic innovation where a randomized study would then be acceptable. Many other explanations could be imagined, and much more information would be needed before one could attempt to assign a cause.

The authors go beyond the frequencies displayed in Table 2 to estimate the size of the treatment effects. For this purpose, they utilize a sophisticated technique, **empirical Bayes**, which is particularly suited for meta-analysis.

Example 10: Literary Detection The Federalist papers are a historically important set of 85 short political essays published mostly anonymously in 1787–1788 by Alexander Hamilton, James Madison, and John Jay. The authorship of most of these papers was eventually established but that of 12 of them has remained in dispute between Madison (M) and Hamilton (H), with a recent historical research leaning toward, but not clearly deciding in favor of, Madison.

An effort to resolve the doubt by statistical methods was undertaken by Mosteller and Wallace [34]. The basic idea of such literary detection is to find aspects of the writing styles of the two (or more) authors in question that have good ability to discriminate between the various possibilities. This was particularly difficult in the present case because the two authors have very similar styles. However, by comparing known texts of M and H, Mosteller and Wallace were able to identify a number of words that were used with much higher frequency by one of the authors than the other. As an illustration, Table 3 shows the frequency of occurrence of the word "on" in blocks of about 200 words from texts by the two authors. (For example, the number of blocks in which the word "on" occurred exactly twice was 27 for the 247 H blocks, but 55 for the 262 M blocks.) The rate of occurrence of the word "on" per thousand words of text was 3.38 for H and 7.57 for M.

Table 3 (a)

	Word frequency of “on” in 200-word blocks							Total number of blocks
	0	1	2	3	4	5	6	
H	145	67	27	7	1	–	–	247
M	63	80	55	32	20	8	4	262

(a) Adapted from Mosteller and Wallace [34]

The present problem is similar to the diagnostic problem of Example 3, with θ taking on the two values H and M. (The statistical methodology dealing with the attribution of an item to one of two or more classes, a patient to a disease, or a piece of writing to an author, is called *classification* or *discrimination*.) Mosteller and Wallace’s first task was to decide on observations X that might provide them with the evidence needed to settle the question. They selected a total of 30 words (including the word “on”) with high discriminating ability, and used as their observations X the frequencies with which these words occurred in a given text of disputed authorship.

Next the distribution $p_\theta(x)$ for the frequency of a given word had to be specified for each author with the help of the known H and M texts. Bayesian analyses for each of the 30 words based on the chosen family of distributions were combined into overall odds for M and H. For all but two of the papers, these overwhelmingly (several hundred million to one) favored Madison, given any reasonable prior odds for M and H. For each of these papers, the analysis leaves little room for doubt. In the remaining two cases Madison is also favored, but the odds are more modest, and the statistical attribution therefore less certain.

Statistical considerations arise in nearly all fields of human endeavor. Many of the associated activities are carried out by large numbers of full- or part-time professional statisticians. The basic training in statistics, as in most other fields, occurs at universities and colleges where departments of statistics offer both undergraduate and graduate degrees in statistics. (At some institutions, the principal statistics courses are instead provided by the mathematics or economics department.) In addition, there may be degrees in biostatistics. Statistics courses and quantitative programs with a strong statistical component may also be offered in operations research, business

schools, demography, economics, education, psychology, and sociology. In addition to courses and programs preparing for a profession in statistics, statistics departments also provide “service courses” both at introductory and advanced levels to students in other fields who may need to use statistical methods in their work.

Another need of statistical education is filled by courses in statistical concepts as a part of general education. Acquiring the ability to think in statistical terms is of great importance, even for persons without a quantitative bent, in view of the pervasive occurrence of statistical ideas in newspapers and magazines, and in the terminology we use to describe and discuss the world around us. What do we mean by saying that women tend to live longer than men, or that cancer patients survive longer today than they did 10 years ago? Does it mean they live longer on the average, that the median length of their life is longer, or that they have a better chance to survive to any given age? And is the longer survival of persons diagnosed to have cancer primarily due to the availability of more effective treatments, including earlier diagnosis? In fact, is there even an increase in length of survival, or is the apparent increase just a statistical consequence of earlier diagnosis? If the disease is diagnosed a year earlier, the survival after diagnosis has increased by a year even if nothing else has changed.

To consider another example, what is meant by the “rate of unemployment”? Roughly speaking, it is the proportion among the people wishing to be employed who are not. But do the official rates include those past seekers for jobs who have given up in despair? A change in the figure for unemployment may be the result of a small change in the definition, or of some sociological change such as the increased entry of women into the workforce.

Many of the considerations involved in such issues are statistical. Fortunately, the basic ideas needed

for general discussion and comprehension can be communicated at a fairly nontechnical level, as is done, for example, in Tanur *et al.* [35], Mosteller *et al.* [33], and Freedman *et al.* [32]. Books such as these, and the increasing availability of first courses in probability and statistics in high schools, should have the effect of gradually raising the general level of statistical literacy.

Acknowledgments

I would like to thank David Cox, Persi Diaconis, David Freedman, William Kruskal, Frederick Mosteller, Juliet Shaffer, and the editors for reading a draft of this article, and providing me with comments and suggestions that resulted in many improvements.

Variables

The notion of recording some feature that is subject to systematic and haphazard variation, and hence the idea of a variable, is all pervasive. In mathematical statistics, *random variable* has a technical meaning, defined in the context of measure theory: random variables are measurable functions from a probability space to a measurable space (see **Probability Theory**). In applied statistics and empirical studies, a variable is a measurable factor, characteristic, or attribute of a product, process, machine, or other experimental unit. When considering products of a production process as the experimental units of interest, one could measure variables such as the products' length, strength, and whether the products are free from scratches.

When a classification of types of variables is attempted, a rather bewildering variety soon emerges. There is the further complication that terminology sometimes varies considerably between different fields, for example between the natural and the social sciences and, within the latter, between psychometrics, sociology, and econometrics.

In some ways the most important classification of variables is *via* their purpose in the particular investigation under study. These distinctions are inevitably context dependent. Variables may be *explanatory*, *intermediate*, or *responses*. That is, the objective of the study is regarded as being the explanation of variability in the *response* in terms of the *explanatory* variables, and *intermediate* variables may be regarded as responses in one stage of the analysis and as explanatory in another stage of analysis. In econometrics the terms *exogenous* and *endogenous* are used, respectively, for variables that are regarded as given from outside and those whose variation is to be explained or modeled. These classes correspond broadly to the explanatory *versus* the others. The older terminology of *independent* instead of explanatory and *dependent* instead of response is probably best abandoned because of potential confusion with statistical independence (see **Dependence**). See also **Covariate**.

Another classification of variables is based on the mathematical structure of the possible values. Thus variables can be one dimensional (univariate) or essentially multidimensional (multivariate),

and forcing essentially multivariate concepts, for example service quality, into one dimension could possibly lead to dire consequences. In one dimension variables may be binary (two possible values), nominal (more than two unordered values), ordinal (ordered values, but without the concept of "distance" among the values), quantitative and essentially integer valued, or quantitative and essentially with a continuous range of possible values. Mixtures of the various types occur quite commonly and can lead to problems of formulation, especially when multidimensional distributions are required. Pass/fail inspection is an example of binary measurement. Classification of production faults into defect types (machine related, material related, operator related, etc.) gives a nominal variable. Classification of faults into ordered classes (severe, major, minor) gives an ordinal variable. Measuring the products' dimensions, strength, or another characteristic gives a quantitative variable. Binary, nominal, and ordinal variables are often called *categorical*, while quantitative variables are often called *numeric*. In industrial statistics and engineering, the terms *attribute* and *variable* are often used instead of categorical and numeric, but this usage of these words deviates from the meaning that the words attribute and variable usually have in the other statistical disciplines.

It is possible to pass down the hierarchy by collapsing, in the extreme case converting, a quantitative measurement into a binary one according to whether the quantitative variable exceeds or does not exceed a given threshold. Sometimes it is helpful either in interpretation or model selection to move in another direction, for example interpreting a binary or ordinal variable *via* a latent continuous variable.

Note that the notion of a continuous range of possible values is often an extremely useful idealization, but in fact all variables as actually recorded are discrete and in some contexts this discreteness must be recognized both in theoretical analyses and in applications. Campbell [1] gave a careful discussion of principles of measurement in the physical sciences. Stevens [2] introduced a classification of quantitative variables, according to differences and/or ratios of corresponding scale points that retain their meaning across the range of values (so-called interval and ratio scales).

Variance Components

Although there is a vast amount of literature dealing with **variance components**, the basic concept is simple. Suppose an observable random variable Y , with variance σ_Y^2 , is the sum $A + E$ of two nonobservable independent variables A and E . Let σ_A^2 denote the variance of A and σ_E^2 denote the variance of E . Then, due to the independence of A and E , $\sigma_Y^2 = \sigma_A^2 + \sigma_E^2$. σ_A^2 and σ_E^2 are called *variance components* of σ_Y^2 .

In a variety of practical problem areas, it is important to make statistical inference statements relative to variance components. As early as 1861, the astronomer Airy [1] concerned himself with telescopic observations of the same phenomenon b_i times for the i th night, for $i = 1, 2, \dots, a$ nights. Airy desired information pertinent to the nightly variation σ_A^2 and the within-night variation σ_E^2 . The essence of Airy's problem is also the essence of problems familiar to many investigators. For illustrative purposes, we consider an example involving quality measurements in a production process. Let Y_{ij} be the quality of the j th product in batch i .

It is helpful to think of the observations Y_{ij} as variables created by adding realizations of variables associated with sampling from two hypothetical populations; one is a population of batch effects and the other a population of nonbatch-related individual products effects. Crucial to the **estimation** procedure is the fact that one realization of an A_i variable is added to several (in this case b) different values of E_{ij} variables. If one E value was added to each A value, then the effects would be confounded and the components σ_A^2 and σ_E^2 would be nonestimable. To describe this situation statistically, we assume the random-effects model $Y_{ij} = \mu + A_i + E_{ij}$, where all variables $A_i, i = 1, \dots, a$, and $E_{ij}, j = 1, \dots, b$, are mutually independent,

$\mathcal{E}[A_i] = 0, \mathcal{E}[E_{ij}] = 0, \text{var}(A_i) = \sigma_A^2$, and $\text{var}(E_{ij}) = \sigma_E^2$. In this setting A_i is the random effect produced by the i th batch and σ_A^2 is the variance component attributable to variation between batches. $E_{ij} = Y_{ij} - \mu - A_i$ is the residual effect or the random individual within-batch product effect and σ_E^2 is the variance component due to variation between products within batches. The problem is to make inference statements relative to σ_A^2 and σ_E^2 . We first focus on point estimates of the components.

To quote Searle [2], who has studied variance components problems in detail, "The basic principle for estimating variance components has been and to a large extent still is, that of equating quadratic functions of the observations to their expected values. Obvious candidates for such functions are those of the analysis of variance (AOV) table."

Suppose $a = 6$ batches are chosen at random from a very large number of batches. Consider the data given in Table 1.

The one-way classification *analysis of variance* (see **Analysis of Variance**) is shown in Table 2.

The estimation procedure is to set numerical values of the mean squares (MSs) equal to expected mean squares (EMS) and solve the resulting equations

$$\hat{\sigma}_E^2 + 5\hat{\sigma}_A^2 = 2.936 \quad (1)$$

$$\hat{\sigma}_E^2 = 0.153 \quad (2)$$

Table 1 Quality of 30 products

Batch	1	2	3	4	5	6
Quality of	4.17	4.83	5.95	4.43	3.86	4.98
individual	5.21	5.70	6.50	4.85	4.12	5.58
products	4.60	5.91	6.34	3.92	4.70	6.10
	4.35	4.92	6.09	4.25	3.90	5.75
	4.54	5.72	5.87	4.64	4.41	5.29

Table 2 AOV for quality data

Source	$df^{(a)}$	$SS^{(b)}$	$MS^{(c)}$	$EMS^{(d)}$
Total corrected	$ab - 1 = 29$	$SST = 18.34$		
Among batches	$a - 1 = 5$	$SSA = 14.68$	$MSA = 2.936$	$\sigma_E^2 + 5\sigma_A^2$
Within batches	$a(b - 1) = 24$	$SSE = 3.66$	$MSE = 0.153$	σ_E^2

^(a)df: degrees of degree ^(b)SS: Sum of Squares ^(c)MS: Mean Squares ^(d)EMS: Expand Value of mean square

2 Variance Components

We find $\hat{\sigma}_A^2 = 0.557$ and thus conclude that the component due to batches are quite large relative to the within-batches component.

Unbiasedness is among the desirable properties that AOV point estimators of variance components enjoy. Among their undesirable properties is the fact that estimates can be negative and indeed often are. Furthermore, no closed form exists for the distribution of estimators such as $\hat{\sigma}_A^2 = (MSA - MSE)/b$. The support for the distribution is all real numbers. AOV estimators are linear combinations of χ^2 related variables.

If the inference mode is testing instead of point estimation (see **Parametric Tests**), the AOV along with normality assumptions give MSs, which are distributed independently as multiples of central χ^2 variables. In particular, for the balanced one-way situation, which we have thus far focused upon,

$$\frac{SSA}{\sigma_E^2 + b\sigma_A^2} \sim \chi^2(a-1) \text{ independent of} \quad (3)$$

$$\frac{SSE}{\sigma_E^2} \sim \chi^2[a(b-1)] \quad (4)$$

Thus under the hypothesis $H_0: \sigma_A^2 = 0$, the ratio $MSA/MSE \sim F\{(a-1), a(b-1)\}$ and serves as a test statistic for testing H_0 versus $\sigma_A^2 > 0$. For the quality data, the F ratio is $F = 2.936/0.153 = 19.25$.

If the inference mode is that of a **confidence interval** (see **Confidence Intervals**), then the procedure varies, for a multitude of suggestions have been presented. The reason for this is that for most components only appropriate interval statements can be derived. An exception is the exact interval statement

$$P \left[\frac{SSE}{\chi_{1-\alpha/2}^2} < \sigma_E^2 < \frac{SSE}{\chi_{\alpha/2}^2} \right] = 1 - \alpha \quad (5)$$

This statement is an immediate consequence of the fact that under normality, SSE/σ_E^2 is distributed as a central χ^2 variable.

An exact interval can be obtained for $\sigma_E^2/(\sigma_A^2 + \sigma_E^2)$ from the fact that

$$\frac{\sigma_E^2}{\sigma_A^2 + \sigma_E^2} \frac{MSA}{MSE} \sim F\{a-1, a(b-1)\} \quad (6)$$

Manipulation of the statement for $\sigma_E^2/(\sigma_A^2 + \sigma_E^2)$ leads directly to probability interval statements for σ_A^2/σ_E^2 and $\sigma_A^2/(\sigma_A^2 + \sigma_E^2)$, the last function being known as the **intraclass correlation**. An overview of methods for the determination of confidence intervals for variance components is given in Burdick and Graybill [3].

The concepts presented for the balanced one-way classification situation can be extended in many ways. Consider three variance components that arise in conjunction with a random-effects model for balanced two-way **factorial** data. Let factor A be studied at randomly chosen levels and factor B at b levels. Denote the observation for the i th level of A and the j th level of B by Y_{ij} and suppose $Y_{ij} = \mu + A_i + B_j + E_{ij}$. The parameters of interest are the variances σ_A^2, σ_B^2 , and σ_E^2 for the respective populations from which A_i, B_j , and E_{ij} were selected. Provided we have a full $a \times b$ factorial experiment (see **Factorial Experiments**) (no missing observations), the AOV procedure is to let

$$MSA = \hat{\sigma}_E^2 + b\hat{\sigma}_A^2, MSB = \hat{\sigma}_E^2 + a\hat{\sigma}_B^2 \quad (7)$$

and $MSE = \hat{\sigma}_E^2$, from which we obtain

$$\hat{\sigma}_A^2 = \frac{1}{b}[MSA - MSE] \quad (8)$$

$$\hat{\sigma}_B^2 = \frac{1}{a}[MSB - MSE] \quad (9)$$

and $\hat{\sigma}_E^2 = MSE$.

Under normality assumptions, the F ratios MSA/MSE and MSB/MSE serve as test statistics for the hypotheses $\sigma_A^2 = 0$ and $\sigma_B^2 = 0$.

Extensions of the basic ideas are not always straightforward. There are complicating factors when:

1. the data are unbalanced,
2. the model is a mixed effects model, and when
3. interactions are present.

One complicating factor is that of determining EMS. Another is choosing among the often many possible quadratic forms to equate with their expectations. Henderson [4] presented three methods, which have been widely used. Method I uses quadratic forms (not necessarily sums of squares (SS)) analogous to those already discussed for the balanced data cases. Method I unfortunately gives biased

estimates of variance components in mixed-model situations. Although this is well known, the ease of the method has made it popular and for mixed-model data two approaches are commonly employed. The first is to ignore the fixed effects and the second is to treat the fixed effects as random effects. Both approaches have been investigated and deemed unsatisfactory.

Henderson's method II was designed to overcome the **bias** problem inherent in method I when applied to mixed models. The idea is to correct the data for the mixed effects and then use method I on the corrected data. The correction process produces correlated error terms, which then lead to a biased estimate of σ_E^2 , but this bias can also be corrected.

Henderson's method of correcting the data for fixed effects is but one of several ways that can and have been applied. This lack of uniqueness detracts from the usefulness of the method. There are other difficulties. If there are interactions between any of the fixed effects with a random effect, then one cannot transform to a model where method I can be directly applied. This is a serious limitation.

Henderson's method III (the fitting constants method) is often employable when methods I and II would be unsatisfactory. The method can be used for any situation. We will illustrate its use in an unbalanced two-way cross-classification situation with interaction. Suppose there are N observations. Let the model be $Y_{ijk} = \mu + \beta_j + A_i + (A\beta)_{ij} + E_{ijk}$. Factor B is fixed but factor A is random as are interaction and error. Suppose s cells contain observations. We desire to estimate the variance components σ_A^2 , σ_{AB}^2 , and σ_E^2 . Seeing there are three components, the method consists of setting three reductions in SS equal to their expectations. The method is not unique. The problem remains unsolved as to which quadratic forms should be used. One choice is to write an AOV for "A after B" (see Table 3).

Table 3 An AOV for two-way unbalanced data

Source	df	Reductions
Levels of B	$b - 1$	$R(\beta \mu)$
A adjusted for B	$a - 1$	$R(A \mu, \beta)$
Interaction adjusted	$s - a - b + 1$	$R(A \times B \mu, A, \beta)$
Error	$N - s$	SSE

$\hat{\sigma}_E^2$ is always estimated from $SSE/(n - s)$ but other choices are

$$R(A \times B|\mu, A, \beta) = C_1 \hat{\sigma}_{A\beta}^2 + (s - a - b - 1) \hat{\sigma}_E^2 \quad (10)$$

and

$$R(A, A \times B|\mu, \beta) = C_2 \hat{\sigma}_{A\beta}^2 + C_3 \hat{\sigma}_A^2 + (s - b) \hat{\sigma}_E^2 \quad (11)$$

Until 1967, Henderson's methods were the only methods used with unbalanced data. Since that year many alternative approaches have been presented. Among these are:

- ML: maximum likelihood.
- REML: restricted maximum likelihood.
- MINQUE: minimum norm quadratic unbiased estimation.

REML is an adaptation of ML (see **Maximum Likelihood**) where the idea is to maximize the likelihood of that part of the sufficient statistics, which is location invariant. It is well known that the ML estimate of the variance in a simple random sample of size b is biased, having divisor b rather than $b - 1$. In more complex models the resulting estimates of variance may be entirely unsatisfactory especially if the number of nuisance parameters is large. The problem is tackled by the REML procedure, which effectively adjusts for **degrees of freedom** (df) lost in estimating parameters in the expected value, and gives estimators of the remaining parameters with less bias and better consistency properties. The idea is to divide the data into two sets of contrasts – one between group means, and another with zero expectation (the error contrasts). The estimates are found maximizing the likelihood function of the error contrasts, excluding the first set of contrasts on the grounds that such contrasts cannot provide information about the variance components. See Searle *et al.* [5] for details.

Control Charts, Overview

History

Control charts originated in the work of Dr. Walter Shewhart, the father of statistical process control, in the 1920s. Shewhart, a physicist by training, was employed by the Western Electric Company, which made early telephone equipment. He was concerned with finding an economical way to monitor and control manufacturing processes in order to yield high quality product. Shewhart knew that external factors beyond the control of production line workers sometimes precipitated process changes that necessitated corrective action. However, he also realized that it required discipline to avoid making frequent unnecessary adjustments that might do more harm than good.

Shewhart's groundbreaking insight, which was quite revolutionary at the time, was to apply statistical concepts to solve this very practical problem. He reasoned that the characteristic variability of a manufacturing process could best be represented in statistical terms. Process changes that required corrective action could then be detected by observing results that were inconsistent with these established statistical norms. The tool Shewhart devised for conducting this comparison was the control chart. He first communicated the concept behind control charts internally in 1924, and subsequently published his approach in various papers and books throughout the 1920s and 1930s (e.g. [1]).

Methodology

Working in an era of extremely rudimentary computational resources, and very limited education among production workers, Shewhart's techniques necessarily had to be simple ones. Consequently, so-called *Shewhart Charts* can be constructed from process data using only basic arithmetic, and tables of statistical constants which Shewhart (and subsequently other researchers) provided. The method was traditionally implemented graphically, with line workers plotting production data over time. The scale of the characteristic being monitored would be on the vertical axis, and the time sequence of the observations on

the horizontal axis (Figure 1). Horizontal lines ("control limits") superimposed on the plot would indicate the typical range of the data; corrective action would be taken only when the plotted values fell outside of these limits (later, other supplementary response rules were added, as well).

The sources of routine variability which are viewed as being intrinsic to a process have come to be called *common causes*. Root causes of atypical variability external to the proper operation of a process have been named *special causes*. A process that is operating properly at a stable level, exhibiting consistent variability in the absence of special causes, is said to be in "statistical control".

Viewed in these terms, the use of Shewhart control charts is intended to let common cause variability pass, but to detect and signal the need for corrective action (called *giving an out-of-control signal*) when special causes are present.

Evolution

Starting with Shewhart, the most common use of control charts throughout their history has been to monitor the level of a product or process property which is measured on a continuous numerical scale, often assumed to be normally distributed (*see Control Charts for the Mean*). Over the intervening decades, however, a vast literature has originated, which extends the uses of control charts to many other domains. Included among these are, for example, control charts for monitoring:

- the level of a continuous characteristic having an arbitrary distribution (*see Control Charts, Nonparametric*);
- the level of a process which is run in short or batch production runs (*see Control Charts for Short Production Runs; Control Charts for Batch Processes*);
- the variability of a process (*see Moving Range and R Charts; Control Charts for the Standard Deviation*);
- process characteristics measured using categorical (also known as *discrete* or *attribute*) data (*see Control Charts for Attributes*);
- processes which by their nature drift over time (*see Autocorrelated Data; Large Autoregressive Integrated Moving Average (ARIMA) Modeling*);

2 Control Charts, Overview

Figure 1 Typical Shewhart control chart for the level of a process

- the level or variability of multiple correlated (“multivariate”) product/process characteristics (*see* **Multivariate Control Charts Overview; Hotelling’s T^2 Chart; Multivariate Exponentially Weighted Moving Average (MEWMA) Control Chart; Multivariate Cumulative Sum (CUSUM) Chart; Multivariate Charts for Variability; Multivariate Control Charts, Interpretation of**);
- and even for monitoring the in-principle infinite-dimensional (e.g., spatial) profile of a property present throughout a material or manufactured part (*see* **Profile Monitoring**).

Many of these techniques make intrinsic use of the extraordinary growth of computational resources that has occurred since World War II. One artifact of this fundamental change in the production environment has been the rise of control charts which make use of computationally intensive techniques (*see*, for example, **Neural Networks: Construction and Evaluation**). Another has been a migration from the traditional manual graphical implementation, to an automated algorithmic approach. Moreover, these monitoring schemes have for some time now been applied to systems of processes, or even on a plant-wide scale [2].

On another dimension, statistical process control techniques have, for a number of years now, found rapidly increasing application outside of their tradition manufacturing origins. The control charting methods mentioned above are seeing use for monitoring and improving nearly all genres of business processes, including, for example, supply

chain and order fulfillment, human resource management, financial and accounting processes, call center management, and many others.

Application Issues

One very useful aspect of research into control charting is that many of the newer techniques (*see* **Exponentially Weighted Moving Average (EWMA) Control Chart; Cumulative Sum (CUSUM) Chart**) are considerably more powerful than those pioneered by Shewhart. As a result, it is now possible to detect process excursions more quickly than before.

It is this speed of detection – the average number of observations (“average run length” (ARL))” after onset of a special cause until it is detected – that is most commonly used as a metric for determining the power and sophistication of a control charting method (*see* **Average Run Lengths and Operating Characteristic Curves**). A common fallacy surrounding the use of control charts is that an out-of-control signal is given immediately at the point in time at which a special cause has occurred. Although this may be true in the case of extremely severe disruptions, control charts usually require some time to detect the process change attributable to a special cause. As one might logically expect, larger changes will generally be detected more quickly, while more subtle effects will take longer to produce an out-of-control signal. Thus the ARL is a useful measure of how promptly one might expect notification of a change, and is a good way of comparing the performance of alternative charting methods in a given situation.

When it is essential to identify when the change actually took place (for example, to aid in determining the identity of the special cause), control charts may be used in conjunction with statistical change-point methods (*see* **Change-Point Methods**).

Another consideration is that all control charts have some likelihood of signaling even when no special cause is present. With properly constructed charts, however, the frequency of such false alarms is generally quite small (typically, once in several hundred observations at most). As a practical matter, judicious use of common control chart types that have been well documented in the literature will allow selection of chart parameters that avoids undue risk of false alarms.

The increasing complexity of control charts also poses a number of challenges for users, however. One example of this is that signals from some chart types are more difficult to interpret than was the case with traditional Shewhart methods (*see*, for example, **Multivariate Control Charts, Interpretation of**). Moreover, the fact that there is now such a wealth of control charting techniques, which overall is a great benefit, nonetheless, makes the selection of which chart type to use, more difficult (*see* **Control Charts, Selection of**). Another consideration is that the power of modern control charting techniques is often such as to enable detection of process changes that are so small as to be of little practical interest.

Related Techniques

Research into process control theory and methods since Shewhart's time has also identified fundamentally different strategies for process control which complement or offer alternatives to control charting. Best known among these are algorithmic feedback or feed-forward techniques which adjust the process in real time with the goal of minimizing variability and thereby maximizing quality (*see* **Engineering Process Control; Feedback Control**). Considerable effort has gone into characterizing what types of process are best controlled using these techniques, or by using control charts, or a combination of both.

Conclusion

On the basis of Shewhart's seminal insight, control charts have evolved from simple beginnings into a

multifaceted process control discipline. Control charting techniques have been developed for monitoring properties of the overwhelming majority of processes encountered in common practice. As a result, statistical process control and related fields such as engineering process control provide business and industry with powerful and easy to use tools for optimizing performance and improving the quality of all kinds of business processes.

Control Charts for the Mean

Introduction with Example

The survey results given in [1] showed that the $\bar{X}$ chart was the most frequently used **control chart**. Although those survey results are of course now out of date, the $\bar{X}$ chart is almost certainly still the most frequently used control chart.

As the name of the chart implies, this is a control chart of averages, and more specifically of subgroup averages that are time ordered. As with every Shewhart control chart for which 3σ limits are used, the control limits are of the general form $\hat{\theta} \pm 3\hat{\sigma}_{\hat{\theta}}$, with $\hat{\theta}$ denoting a function of the statistic that is plotted on the chart, which serves as the centerline on the chart, and $\hat{\sigma}_{\hat{\theta}}$ denotes the estimator of the standard deviation of $\hat{\theta}$.

The control limits for the $\bar{X}$ chart are thus computed as $\bar{\bar{X}} \pm 3\hat{\sigma}_{\bar{X}}$, with $\bar{\bar{X}}$ denoting the average of the subgroup averages $\bar{X}$, obtained ideally from recent data, and $\hat{\sigma}_{\bar{X}}$ denotes some estimator of the standard deviation of the subgroup averages. That estimator is typically either $(\bar{s}/c_4)/\sqrt{n}$, with $\bar{s}$ denoting the average of the subgroup standard deviations and c_4 the tabular value for a given subgroup size, or $(\bar{R}/d_2)/\sqrt{n}$, with $\bar{R}$ the average of the subgroup ranges and d_2 the tabular value for a given subgroup size. (The values of c_4 and d_2 are those that make the respective estimators unbiased estimators of σ_x . Some values of c_4 are given here in Table 1.)

To illustrate, using subgroup standard deviations in estimating σ_x , let us assume that 40 subgroups of size 5 are available from recent data, with $\bar{\bar{X}} = 36.79$, $\bar{s} = 3.3853$, and $c_4 = 0.9400$ from Table 1. The control limits would then be computed as $\bar{\bar{X}} \pm 3(\bar{s}/c_4)/\sqrt{n} = 36.79 \pm 3(3.3853/0.94)/\sqrt{5} = (31.96, 41.62)$. Thus, the lower control limit (LCL) is 31.96 and the upper control limit (UCL) is 41.62, with the midline on the chart being $36.79 (= \bar{\bar{X}})$.

The chart is shown in Figure 1 and it can be observed that all of the points are within the control limits. This suggests that the process was in control in Phase 1.

Note: Control charts are sometimes constructed using assumed or desired parameter values. This is

highly inadvisable because an out-of-control signal could simply mean that a process was out of control relative to desired parameter values that might not be attainable under current conditions. We want to see whether a process is stable or out of control relative to its current capability.

If any of the 40 subgroup averages had plotted outside the control limits, a search for an **assignable cause** would be performed in an attempt to determine the cause(s) of the aberrant point(s). If the cause(s) could be both identified and removed, the control limits would be recomputed and the process continued until either all of the plotted points are inside the control limits or causes of points outside the limits cannot be determined, or if determinable causes, are not removable.

The end of this process would be the end of Phase I, to be followed by real-time process monitoring, which is Phase II.

In order for the control limits that are determined at the end of Phase I to have good properties (especially properties that deviate only slightly from the properties when parameter values are assumed known), and not have sampling variability that is deemed unacceptably high, the limits should be computed from a reasonably large number of observations from the assumed in-control distribution (see, e.g., [2]). In this example, there were 200 observations, which is less than preferred. Therefore, it would be better, while ostensibly operating in Phase II, to add about 20 more subgroups of size 5 to the Phase I data after the data from the 20 subgroups have been collected in real time. The “semipermanent” control limits would then be recomputed using the 60 subgroups of size 5 if the Phase II monitoring showed the process to apparently be in control when the new points were plotted.

Table 1 Selected values of c_4

10	0.9727

2 Control Charts for the Mean

Figure 1 $\bar{X}$ -chart

Of course eventually the control limits will have to be recomputed as processes change over time and control limits should be based on recent data. When new control limits should be computed is a matter of judgment.

Since subgroups are involved, the subgroup size must be determined. Historically, subgroups of four or five observations have frequently been used. The results of a survey of 117 companies in the food manufacturing/processing and metalworking industries were reported in [3], with the respondents asked to provide the subgroup size that they typically used. Unfortunately, the author, Osborn, did not provide any summary statistics regarding subgroup size, but instead gave the average **power** (i.e., probability) of detecting, with the first plotted point, a (minimum) shift that the respondent believed was crucial. If we assume normality and known parameter values, it can be shown that the power of detecting a $1\sigma_x$ shift (either increase or decrease) on the first plotted point after the shift with a subgroup size of 5 is 0.22, and 0.45 for a subgroup size of 6. (Note that the shift is here stated in terms of σ_x , not $\sigma_{\bar{x}}$. If the shift were stated in terms of $\sigma_{\bar{x}}$, the power would be a function only of the amount of the shift and be independent of the subgroup size.) Since the average power reported by Osborn was 0.3426, the average subgroup size was

probably about 5, assuming that the shift was $1\sigma_x$ and was constant over the respondents.

A large subgroup size should be avoided (just as very large sample sizes should be avoided with any tool of statistical inference), as this would make the control chart too sensitive to very small mean shifts that are considered to be inconsequential. Indeed, Box in [4] stated, in responding to the question of whether statistical control can be achieved: "The truth is that we all live in a nonstationary world; a world in which external factors never stay still. Indeed the idea of stationarity – of a stable world in which, without our intervention, things stay put over time – is a purely conceptual one." If we accept this, then we should strive for processes being in a state of near statistical control and not be concerned by what might seem to be very small mean shifts.

As with any statistical procedure for detecting change, the user would have to determine the minimal shift that is important to detect as quickly as possible, and then decide if the selected subgroup size provides sufficient power for detecting that amount of shift. (Although the $\bar{X}$ chart is reasonably good at detecting large shifts, there are other process control procedures, such as cumulative sum (**CUSUM**) procedures and **exponentially weighted moving average** (**EWMA**) procedures that are better for detecting small mean shifts.)

Assumptions

With every statistical procedure, it is important to recognize the assumptions that underlie the procedure and to test those assumptions, not leaving anything to chance. For an $\bar{X}$ chart, the basic assumptions are that the data are approximately normally distributed and are independent, both within subgroups and between subgroups.

The normality assumption might be questioned by some, but if the distribution of the data is highly skewed and/or the population distribution is believed to be highly skewed based on the nature of the process characteristic, there will also be considerable **skewness** in the distribution of subgroup averages computed from five observations. In that case, it would be inappropriate to use control limits that are symmetric about $\bar{\bar{X}}$.

Nonnormality can be assessed through a normal **probability plot** of the data or of the subgroup averages if there is a sufficient number of them, and numerical tests for normality are also available. If the collected data should be approximately normal but instead are markedly nonnormal, this might be a signal that the process is out of control. In that case, bringing the process into a state of statistical control may remedy the problem. If a process is in control and the data are markedly nonnormal, it might be possible to transform the data to approximate normality, such as by using a Box–Cox transformation (see [5]). For more discussion of the normality issue for subgroup data, see [6] and [7].

The assumption of independence is also important since a lack of independence will, strictly speaking, invalidate the control limits computed under the assumption of independence. Lack of independence can be ascertained through a simple time sequence plot of the data and/or by constructing an **autocorrelation** plot.

As with nonnormality, a lack of independence (i.e., autocorrelated data) could signal that a process is out of control. A classic example of this was given in [8], which was originally published in *Industrial Quality Control* in 1949. Tooling data exhibited a very strong trend, almost like a sine curve. The control chart of subgroup averages indicated control, but many of the individual values did not even meet engineering specifications. The trend was not discovered until the individual observations were plotted. (It will sometimes be necessary to construct a

plot of individual observations even though a control chart for averages is being used.)

If autocorrelation is a normal part of a process, the control limits should be adjusted appropriately, as, for example, in [9]. One often-suggested remedy is to sample less frequently, thus removing or at least reducing the autocorrelation. This is not a good idea as tight control of a process could then be lost. It is best to maintain the normal sampling frequency.

The Possible Use of $k\sigma$ Limits

As with every other type of control chart, there is the option of using $k\sigma$ limits rather than 3σ limits. 3σ limits have historically been used because they offer a reasonable balance between false alarms and quick detection of a parameter change. In some fields of application, quick detection may be far more important than false alarms. For example, in [10] the author mused that 2σ limits might sometimes be more appropriate in clinical care applications.

Individuals Charts

It is not always possible or practical to form subgroups, so individual observations are often plotted instead of subgroup averages. When this is the case, the control limits are obtained from $\bar{X} \pm 3\hat{\sigma}_x$ and various labels have been used for the chart, including an individuals chart (*I* chart) and an *X* chart. Without subgrouping, there is no obvious way to measure short-term variability, however. The common way to overcome this problem is to compute “moving subgroups” of size two. (There will be $n - 1$ such subgroups for n observations.) The range is computed for each subgroup and $\hat{\sigma}_x = \overline{MR}/1.128$, with $\overline{MR}$ denoting the average of these (moving) ranges.

This is appropriate for Phase I. For the start of Phase II, it is better, as shown in [11], to use $\hat{\sigma}_x = \bar{s}/c_4$, with $\bar{s}$ as previously defined and c_4 the tabular value corresponding to the number of observations. (The data used to compute the estimate would be the data not discarded in Phase I.) Specifically, this estimator has a smaller variance than the estimator computed from the moving ranges. It is better to use the latter for Phase I, however, since that estimator is less influenced by extreme data points, thus giving

the chart greater power for detecting points that correspond to an out-of-control condition. Thus, different estimators should ideally be used in each Phase.

It is especially important that the assumption of (approximate) normality be checked when plotting individual observations, as well as checking the assumption of independence. When these assumptions are not met, the chart can have undesirable properties.

Software Usage

The control limits can be computed most efficiently using computer software, and much commercial software is available for control chart construction. Once the limits have been computed, however, points could easily be hand plotted on a chart, if desired, although a calculator would be necessary to compute each subgroup average. This obviously is not the easiest way to do it, however.

Summary

Two charts for controlling a process mean have been described in this article: an $\bar{X}$ chart and an X chart. For a mean shift of a given size, the $\bar{X}$ chart has the greater power of detection but it is not always possible to form subgroups. The normality assumption is especially important for the X chart but should also be checked for the $\bar{X}$ chart. The independence assumption is also important for both charts.

THOMAS P. RYAN

Exponentially Weighted Moving Average (EWMA) Control Chart

Introduction

The exponentially weighted moving average (EWMA) chart first appeared in the statistical **quality control** literature approximately 50 years ago. Roberts [1] introduced the procedure, which he called the *geometric moving average*, as an alternative to the standard Shewhart **control chart** with zone tests. He concluded that the EWMA was more effective than the standard control chart at detecting small changes in the process mean (*see Control Charts for the Mean*). The EWMA has since been studied extensively as a process monitoring tool used to detect both process mean and process variance shifts (*see Control Charts for the Standard Deviation*). More recently (see Vander Wiel [2], for example), the EWMA has appeared in the statistical quality control literature as a bridge between statistical process monitoring and engineering feedback control (*see Engineering Process Control*). That is, it has been presented as a tool that can be appropriately used for either the detection of process changes, or to estimate the mean of an autocorrelated process for the purpose of feedback control. In this article, we will review both applications of the EWMA, and will discuss strengths and weaknesses associated with applying the EWMA in either case. We will also briefly discuss some of the many modifications and enhancements of the EWMA that have appeared in the literature.

Process Monitoring

Detection of Mean Shifts

Most of the statistical quality control literature regarding the EWMA has focused on the problem of detecting a shift in the process mean. It is typically assumed that the process mean μ shifts from a nominal mean μ_0 to a new process average $\mu = \mu_0 + \Delta$, where Δ represents the amount of shift. In the absence of any process upsets, $\Delta = 0$. The purpose of the control chart is to detect the mean shift,

identify the **assignable cause**, and return the process average to nominal.

The EWMA is defined, for a series of observations $y_1, y_2, \dots, y_t, \dots$, by

$$E_0 = \mu_0 \quad (1)$$

$$E_t = (1 - \lambda)E_{t-1} + \lambda y_t, \quad 0 < \lambda \leq 1,$$

$$t = 1, 2, 3, \dots \quad (2)$$

The EWMA has the property that the most recent observation receives the greatest amount of weight, and all previous observations receive weight decreasing exponentially from the most recent to the first observation. The y_t 's can be individual observations or, in many cases, sample averages. If each of the y_t 's has mean μ_0 , E_t also has mean μ_0 . When the process mean shifts to $\mu = \mu_0 + \Delta$, the mean of E_t shifts away from μ_0 and the process is considered "out of control". If the y_t 's are independent with common standard deviation σ , it is easy to show [1] that the standard deviation of E_t is

$$\sigma_{E_t} = \sigma \times \sqrt{\frac{\lambda}{2 - \lambda} [1 - (1 - \lambda)^{2t}]} \quad (3)$$

with limiting value

$$\sigma_E = \sigma \times \sqrt{\frac{\lambda}{2 - \lambda}} \quad (4)$$

The control chart limits are usually defined in terms of this limiting value, set at

$$\mu_0 \pm k\sigma_E \quad (5)$$

The control chart is specified by choice of λ and k . The performance of the EWMA is usually measured in terms of the average number of observations until the control chart produces a signal. This metric is referred to as the average run length (ARL, *see Average Run Lengths and Operating Characteristic Curves*). The ARL depends on the particular choice of λ and k and the shift Δ in the process mean. Various ways of evaluating the ARL and identifying the best choices of λ and k have been proposed in the literature.

Roberts [1] evaluated the ARL of the EWMA by simulating a series of independent observations with a shift in the mean introduced into the process. Crowder [3] showed that the ARL, as well as other

2 Exponentially Weighted Moving Average (EWMA) Control Chart

moments of the run length, could be represented as an integral equation, solvable with simple numerical methods. A computer program to solve the integral equation appeared in [4]. Lucas and Saccucci [5] showed that the ARL, as well as other moments of the run length, could be represented as a Markov chain, also solvable with simple numerical methods. A computer program to solve the **Markov chain** appeared in [5]. These papers assumed a normal process model for the observations; however, the results can be extended to other distributions.

Given the ARL performance of competing EWMA schemes, the optimal chart can be easily determined. Crowder [3] presented a two-step approach to choosing an optimal (λ, k) combination. The first step involved choosing λ to minimize the ARL for a given process shift of interest ($\Delta \neq 0$). The second step involved choosing k to give the desired ARL for the nominal process mean ($\Delta = 0$). Lucas and Saccucci [5] outlined a similar design procedure also based on ARLs.

The properties of the EWMA for the process mean and optimal EWMA design strategies have been thoroughly investigated by numerous authors. The conclusions have consistently been that smaller values of λ are optimal for detecting small shifts in the process mean, and that the EWMA outperforms the standard Shewhart chart for that special case. For very large shifts in the process mean, the Shewhart chart is optimal.

Detection of Variance Shifts

Although most applications of the EWMA have concentrated on the process mean, the more important problem for quality control practitioners is the problem of detecting and removing causes of increased process variation, which typically have greater impact on product quality. Recently, much more attention has been paid to this important problem.

Crowder and Hamilton [6] proposed an EWMA to monitor a process standard deviation based on the observations $y_t = \ln(s_t^2)$, where the s_t^2 values are successive sample variances, each based on subgroup size n . The log transform was recommended for variances of normally distributed data, as the logarithms will be much closer to normally distributed than the sample variances themselves. The EWMA was defined as

$$E_t = \max \left\{ (1 - \lambda)E_{t-1} + \lambda y_t, \ln(\sigma_0^2) \right\}, \quad 0 < \lambda \leq 1,$$

$$t = 1, 2, 3, \dots \quad (6)$$

with $E_0 = \ln(\sigma_0^2)$. The one-sided control chart limit was set at $k\sigma_E$, where σ_E is the limiting standard deviation of E_t , approximated by

$$\sigma_E \approx \left(\frac{\lambda}{2 - \lambda} \right) \left(\frac{2}{n - 1} + \frac{2}{(n - 1)^2} + \frac{4}{3(n - 1)^3} - \frac{16}{15(n - 1)^5} \right) \quad (7)$$

Note from equation (6) that the EWMA is reset to $\ln(\sigma_0^2)$ if its value ever falls below $\ln(\sigma_0^2)$. This is owing to the fact that the primary interest is in increases in process variability. An integral equation was developed to allow easy computation of the ARL for the one-sided EWMA, and a design strategy using those ARLs was presented. A computer program to compute the ARLs appears in [7]. The authors concluded that small λ values are optimal for detecting small percent increases in process standard deviation, while large values of λ are optimal for detecting large percent increases. The authors also concluded that the EWMA outperforms the standard Shewhart range chart for detecting small increases in the process standard deviation. These conclusions were not surprising, as the log transformation tends to “normalize” the data and turn the problem into one of detecting shifts in a process mean.

MacGregor and Harris [8] provided a brief overview of other uses of the EWMA to monitor process variation. They also proposed using “exponentially weighted moving variance” and “exponentially weighted mean squared deviation” charts to monitor process variation. They concluded that the charts are particularly useful when only individual observations are collected and when observations are positively correlated. Gan [9] investigated the properties of “omnibus” EWMA charts designed to detect shifts in both the process mean and the variance with a single chart, but found them to be ineffective. He concluded that the best approach is to design the EWMA mean chart and the one-sided EWMA variance charts separately, as described above.

Strengths and Weaknesses

The major strengths of the EWMA include its simplicity and its ability to quickly detect small shifts in the process mean or variance. These conclusions are reached for idealized models with independent,

identically distributed, normal observations. It is also typically assumed that the parameters of the **normal distribution** are known and are constant until some process upset causes a shift in value.

Numerous modifications to the EWMA chart have been proposed to address failures in the assumptions and specific weaknesses in the approach. One failure in the assumptions is that the process parameters may not be known and must be estimated from the data. Jones and Champ [10] investigated the performance of the EWMA chart with estimated parameters and concluded that **estimation** of the parameters can lead to substantially more frequent false alarms and reduce the sensitivity of the EWMA to detect changes in the process mean. The authors show how the ARLs are affected by estimation and what sample sizes are necessary to apply the standard EWMA procedures without modification.

A weakness of the EWMA involves its inability to quickly detect both small and large shifts in the process mean with a single chart. Lucas and Saccucci [5] proposed a combined Shewhart-EWMA chart, which is constructed by adding Shewhart limits to an EWMA control chart. They also table ARLs of the proposed combined chart and give design recommendations. Capizzi and Masarotto [11] proposed an adaptive EWMA to address the same problem in a single chart. The weighting constant λ is replaced by an adaptive weighting function. The proposed weighting function is constructed to respond to either small or large process shifts. The authors conclude that the adaptive EWMA provides reasonably balanced protection against shifts of different sizes.

Another weakness of the EWMA has been called the *"inertia" problem*. The inertia problem may occur if the process mean is off target when the EWMA is initiated. This could happen because of startup problems or because of ineffective control actions taken after the previous process alarm. When the value of λ is small, it may take the EWMA more time than desirable to react to the process being off target. Lucas and Saccucci [5] proposed a "fast initial response" (FIR) feature to address this problem. The FIR feature is obtained by implementing two one-sided EWMA's, each with an appropriate head start. Instead of initializing a single EWMA with the nominal mean, one of the one-sided EWMA's has a starting value above the nominal mean and the other one-sided EWMA has a starting value below the nominal mean. If the process is off target at startup,

one of the EWMA's will give a signal more quickly than a single two-sided EWMA.

The traditional use of the EWMA in the statistical quality control literature has been to detect shifts in either the mean or the variance of an independent, identically distributed normal process. In the sections that follow, we will address the use of the EWMA for monitoring autocorrelated processes, and how the EWMA can appropriately be used as a feedback control tool.

Feedback Control and Monitoring

Many manufacturing processes have continuous flows of material that produce correlations over consecutive measurements. In these cases, past data are useful for predicting future observations and it is natural to use those predictions for active feedback regulation (*see Engineering Process Control; Feedback Control*). In this context, EWMA's can usefully play three distinct roles: forecasting, compensation, and monitoring. These are discussed in the sections titled "EWMA's for Prediction", "EWMA's for Feedback Control", and "EWMA's for Monitoring Controlled Processes".

Brief Overview of Literature

Kalman [12] revolutionized prediction and control of dynamic systems by introducing a filter to calculate minimum variance predictions through sequential updating. The EWMA update is a special case of the Kalman filter and is the optimal one-step-ahead forecast for an integrated moving average (IMA) process. Trigg [13] used EWMA's to monitor the performance of a forecasting system. His monitoring signal is the ratio of an EWMA of forecast errors to an EWMA of their absolute values. Bather [14] and Box and Jenkins [15] made an interesting connection between EWMA charts and optimal feedback control. They showed that incorporation of a fixed cost for any nonzero adjustment to an IMA process results in an optimal regulation policy that adjusts only when an EWMA statistic falls outside of certain upper and lower dead-band limits. A follow-up paper of Box *et al.* [16] contrasts the function of control charts for monitoring with that of control algorithms for process regulation.

The discussion paper of Box and Kramer [17] explores interrelationships between feedback control

4 Exponentially Weighted Moving Average (EWMA) Control Chart

and process monitoring and the use of EWMA's in both contexts. Vander Wiel *et al.* [18] call the combination of control and monitoring *algorithmic statistical process control* (ASPC). They use EWMA's to regulate viscosity in a batch polymerization reaction and then apply a cumulative sum (CUSUMs) as a monitoring scheme (see **Cumulative Sum (CUSUM) Chart**). Box and Luceño's book [19] includes derivations and examples of EWMA's for optimal prediction and control and for process monitoring.

EWMA's for Prediction

Exponential smoothing has been widely used for forecasting **time series** [20]. Single exponential smoothing uses an EWMA of the time series to predict the next value. This minimizes the variance of forecast errors, if the time series is a so-called IMA and the EWMA parameter matches the time series model, as shown below.

Industrial processes that tend to wander are sometimes modeled as random walks. The IMA is a slightly more general model that is equivalent to noisy observation of a random walk. The usual description of an IMA process, N_t (N stands for noise) is

$$N_t = N_{t-1} + a_t - \rho a_{t-1} \quad (t = 1, 2, \dots) \quad (8)$$

where $-1 < \rho < 1$, the a_t are independent "innovations" with mean zero and constant standard deviation, and the recursion starts with $N_0 = a_0$. If $\rho = 0$, N_t is a random walk. (See **Large Autoregressive Integrated Moving Average (ARIMA) Modeling** for additional methods of time series modeling.)

Taking an EWMA of the process N_t for the purpose of forecasting is known as *single exponential smoothing*:

$$\hat{N}_{t+1|t} = (1 - \lambda)\hat{N}_{t|t-1} + \lambda N_t \quad (9)$$

If the EWMA parameter λ is set equal to the IMA parameter ρ , then a little algebra provides the forecast error

$$e_{t+1} \equiv N_{t+1} - \hat{N}_{t+1|t} = a_{t+1} \quad (10)$$

which has the smallest possible variance of any forecast based on $(N_0, \dots, N_t)$. That is, for an IMA process, the best one-step-ahead forecast is an EWMA of the past observations.

EWMA's for Feedback Control

Box and Kramer [17] note that the IMA model can be thought of as an interpolation between an uncorrelated noise process and random walk. They say it "occupies a central place in representing the behavior of many nonstationary disturbances" that impact industrial processes. If N_t represents the "noise" affecting a linear system, then the forecast $\hat{N}_{t|t-1}$ is natural to use for feedback control. A general linear system with IMA noise is

$$Y_{t+1} = \alpha + \beta X_t + f(X_{t-1}, X_{t-2}, \dots) + N_{t+1} \quad (11)$$

where Y_{t+1} is an observation of the system at time $t + 1$, X_t is the setting of a control variable and $f(X_{t-1}, X_{t-2}, \dots)$ is the sum of the linear effects of previous control settings. To steer the system toward a target T , we set

$$T = \alpha + \beta X_t + f(X_{t-1}, X_{t-2}, \dots) + \hat{N}_{t+1|t} \quad (12)$$

and solve for X_t . Here, $\hat{N}_{t+1|t}$ is defined by equation (9) with N_t determined from equation (11). The resulting feedback adjustment rule is

$$X_t = -\beta^{-1} \left[\alpha + f(X_{t-1}, X_{t-2}, \dots) + \hat{N}_{t+1|t} - T \right] \quad (13)$$

and plugging this rule into equation (11) shows that the regulated process becomes

$$Y_t = T + a_t \quad (14)$$

No other regulation scheme gives as small a mean squared error (MSE) between the process and target value. That is, the feedback rule equation (13) based on an EWMA of the process noise is the minimum MSE controller. The above discussion assumes knowledge of the parameters $\lambda = \rho$, α , β , and $f(\cdot)$. Luceño [21] discusses estimation of the best λ for feedback control in cases where ρ is not known or the noise process is not an IMA.

EWMA's for Monitoring Controlled Processes

The previous sections showed how EWMA's can be used for prediction and regulation of a process that tends to wander. However, a sequence of forecasts or a regulated process also needs to be monitored – and

various control charts, including EWMA charts, have been suggested for this role.

Vander Wiel [2] evaluates the use of an EWMA control chart of forecast errors, $e_t = N_t - \hat{N}_{t|t-1}$ to detect a step change in an IMA process and provides guidance on choosing the EWMA control chart parameter. Montgomery *et al.* [22] compare various control charts, including EWMA, applied to forecast errors for detecting upsets that occur within an autoregressive moving average process.

Various authors recommend applying control charts to the *control inputs* X_t or the *controlled outputs* Y_t or both series when a process is run under feedback control. Runger [23] discusses this issue and concludes that, rather than using either inputs or outputs, a more sensitive monitoring procedure is to generate the one-step-ahead forecast errors, e_t , and use a control chart, such as an EWMA, that is tuned to detect process shifts of specified magnitudes.

Strengths and Weaknesses

EWMA is versatile. They can be used for prediction and feedback regulation as well as detection of sudden changes in autocorrelated and regulated processes. A strength of EWMA for prediction and regulation is their simplicity. They are easy to understand and they can produce good forecasts (or form the basis for good feedback regulation) on a wide range of processes with positive **autocorrelation**. On the other hand, EWMA is only optimal for processes with IMA noise structure. For other autocorrelation structures better forecasts can be achieved using time series modeling (*see Large Autoregressive Integrated Moving Average (ARIMA) Modeling*). Similarly, feedback control based on EWMA can be suboptimal. Sometimes better results are achieved using more general control algorithms such as proportional integral derivative (PID) controllers or optimal controllers based on time series modeling (*see Engineering Process Control; Feedback Control*).

Use of EWMA to monitor forecasts or regulated processes is similar to the conventional use of EWMA for process monitoring; however, determining performance properties such as ARLs is more complicated. If forecasts are not optimal, then the forecast errors being monitored will be autocorrelated and this can have a large impact on ARL properties of EWMA control charts. Furthermore, feedback control will act on an abrupt shift in the level of a

process and bring the resulting system output back to the target level. Often, if a shift is not detected within a short “window of opportunity” it will be missed altogether. This complicates the analysis of control chart performance. See [2] for an example.

Finally, using EWMA for forecasting, regulation, and monitoring of forecasts and regulated processes requires a more sophisticated approach to process improvement than conventional control charts. These applications combine time series modeling and parameter estimation, automatic control theory, and control chart design. Many organizations are not equipped with engineers or statisticians that are proficient in each of these areas.

Summary

An EWMA follows the ups and downs of process data; however, it is much smoother than the sequence of raw measurements because each new data point gets averaged in with the previous EWMA value. EWMA control charts are good at detecting small shifts in a process mean or variance and can be combined with Shewhart charts to enhance the ability to quickly detect large process shifts. They can also be initialized with head starts to produce a signal more quickly if the process mean is off target when the EWMA is initiated.

EWMA is also used for forecasting autocorrelated processes, for feedback regulation and for monitoring forecast errors and regulated processes. These advanced uses of EWMA draw on technologies from control charts, time series modeling, and automatic control.

Cumulative Sum (CUSUM) Chart

Introduction

In any manufacturing process, variations in the quality of products always exist and they can never be completely eliminated. In other words, no two products can be completely identical in all aspects. These variations are either inherent in a process or are due to some assignable causes. The inherent variation is due to the cumulative effects of many random causes peculiar to a process. No single cause can account for any major part of the inherent variation. If a process is properly optimized using some experimental design procedures (*see Factorial Experiments; Fractional Factorial Designs; Response Surface Methodology; Assessment of Experimental Designs*), the inherent variation can be kept small. The variations due to assignable causes are relatively larger and these causes include changes in process settings, changes in raw materials, or human errors. A process in the presence of assignable causes is considered to be out of control. A control chart (*see Control Charts, Overview; Control Charts for the Mean*) is a charting procedure designed to detect the presence of assignable causes. One will have a better understanding of the cumulative sum (CUSUM) chart if it is compared to the Shewhart chart.

Consider a process in which there is an in-control measurement of a certain quality characteristic and any deviation from this value is not desirable. In the Shewhart control charting procedure, samples are taken at regular intervals and the sample mean of measurements is plotted against the sample number. A signal is issued for any sample mean falling beyond certain chart limits. The sensitivity of the Shewhart chart is determined by the change in the proportion of sample means falling outside these limits, which in turn depends on the shift in the process mean. This change will be small if the shift is small and thus the Shewhart chart is not sensitive in detecting small shifts. For a chart to be sensitive in detecting a small shift, past samples as well as the most recent sample will have to be utilized in signaling. The CUSUM chart introduced by Page [1] is one such chart. The CUSUM chart can also be used to provide an estimate

of the process mean although this estimate is a poor one.

Let $Y_1, Y_2, \dots$ be the measurements of a certain quality characteristic. These measurements are assumed to be independent and identically distributed normal random variables with mean μ and variance σ^2 (*see Normal Distribution*). Also assume that the in-control mean and variance are given as μ_0 and σ_0 , respectively. The original measurements can be standardized as $X_t = (Y_t - \mu_0)/\sigma_0, t = 1, 2, \dots$ which will have a standard normal distribution. The upper-sided and lower-sided CUSUM charts are obtained by plotting

$$S_t = \max\{0, S_{t-1} + X_t - k\}, \quad t = 1, 2, \dots \quad (1)$$

and

$$T_t = \min\{0, T_{t-1} + X_t + k\}, \quad t = 1, 2, \dots \quad (2)$$

against the sample number t , respectively. The chart parameter k is a positive constant and the initial values $S_0 = u, 0 \leq u < h$ and $T_0 = v, -h < v \leq 0$ are usually chosen to be 0. The upper-sided CUSUM chart, which is intended for detecting an upward shift in the mean will issue a signal when $S_t > h$. Similarly, the lower-sided CUSUM chart which is intended for detecting a downward shift in the mean will issue a signal when $T_t < -h$. The quantities h and $-h$ are usually known as the *chart limits*.

Sensitivity of CUSUM Chart

The sensitivity of a CUSUM chart in detecting a small shift is best illustrated using a simulated data set. In Figures 1–3, we consider a data set in which the first 50 measurements were simulated from a normal distribution with mean 0 and variance 1, and the last 10 with mean 1 and variance 1. The chart parameter k is set at 1 and chart limits of the CUSUM charts are selected such that jointly they have the same in-control average run length (ARL, *see Average Run Lengths and Operating Characteristic Curves*) as the Shewhart chart with 3σ limits. For the first 50 measurements, all the charts show no unusual pattern which corresponds to an in-control process. The shift in the mean occurs after the 50th measurement and Figure 1 shows that the Shewhart chart is unable to detect the presence of such a shift. This shift is clearly reflected as a

2 Cumulative Sum (CUSUM) Chart

Figure 1 Shewhart chart

Figure 2 Upper-sided CUSUM chart

Figure 3 Lower-sided CUSUM chart

slope on the upper-sided CUSUM chart after the 51st sample and a signal is issued at the 59th sample. The lower-sided CUSUM chart shows complete inactivity after the 50th measurement. This example clearly demonstrates the sensitivity of the CUSUM chart in detecting a small shift.

Unfortunately, it is this strength that makes the CUSUM chart less sensitive in detecting a big

shift. This fact is revealed in Figures 4 and 5. In this data set, the first 50 measurements were simulated from a normal distribution with mean 0 and variance 1, and the last four with mean 2.5 and variance 1. The presence of such a big shift is immediately detected by the Shewhart chart and it signals at the 51st sample. This shift is also detected by the CUSUM chart, but it issues a signal only at

Figure 4 Shewhart chart

Figure 5 Upper-sided CUSUM chart

the 54th measurement because it only accumulates $X_t - k$ each time. The worst scenario for the CUSUM chart happens when a shift occurs and the CUSUM is at zero. If sampling is done once every hour, three samples slower in signaling would translate into 3 h of nonconforming products.

Other Aspects of CUSUM Chart

An alternative implementation of the CUSUM chart is the use of the V-mask introduced by Barnard [2], but mathematically both implementations are identical in the sense that when one signals, the other one will signal too. The V-mask implementation is not popular because points plotted could be in an increasing or decreasing trend for a long period (which means plotting out of a piece of paper) and yet does not trigger any signal. The CUSUM chart is often used to estimate the process mean (*see Estimation*) after a signal is issued and this can be done using $\hat{\mu} = k + S_t/N_t$ [3, p. 394 or p. 27; 4] where N_t is the number of samples since the chart became last

active. This formula is actually the same as the mean of the sample means since the chart became last active. As this estimator is associated with a signal, it is biased for all values of the process mean except for one value where it is unbiased. The ARL of a CUSUM chart can be studied using the integral equation approach [1] or the Markov chain approach [5]. In terms of weighting of samples for signaling, the CUSUM chart is perhaps the most intelligent when compared to the exponentially weighted moving average (EWMA, *see Exponentially Weighted Moving Average (EWMA); Exponentially Weighted Moving Average (EWMA) Control Chart*) and the straight moving average (SMA, *see Moving Averages*) charts. Hunter [6] showed that while the EWMA and SMA charts always weight the past samples in a deterministic fashion, the CUSUM chart will only include those when it first senses ($X_t > k$) that the process could be out of control. When it is convinced ($S_t = 0$) that the process is in control, it discards all past samples and starts a new.

When a process is first started and one suspects that the process might not start in an in-control state, Lucas and Crosier [7] suggested using S_0 and T_0 that are nonzero for a faster detection. Combined Shewhart–CUSUM scheme [8] and simultaneous CUSUM schemes [9] could be used to improve the performance of the CUSUM chart. The CUSUM chart is similar to the sequential probability ratio test (SPRT) Moustakides [10] proved that the CUSUM chart is optimal in its run-length performance. Gan [11] provided a simple procedure for the design of an optimal CUSUM chart. A more comprehensive treatment of the CUSUM charts can be found in Hawkins and Olwell [4]. A multivariate CUSUM scheme (see **Multivariate Control Charts Overview–Multivariate Control Charts, Interpretation of**) will have to be employed in processes where the quality is characterized by multiple quality measurements. One approach is to implement a chart using a single monitoring statistic summarized from the multivariate data in each sample. Another approach is to compute a CUSUM statistic for each quality variable. These statistics can either be monitored individually or be combined into a single monitoring statistic on a control chart. Woodall and Ncube [12], Crosier [13], Healy [14], Lowry *et al.* [15], and Mason *et al.* [16] have more detailed discussions of various multivariate charting procedures.

FAH FATT GAN

Moving Range and R Charts

Introduction

The quality of a manufactured item is often measured by one or more quality measurements. This measurement(s) varies from item to item following a (joint) distribution. The parameter or parameters of the (joint) distribution of the quality measurement(s) are measures of the quality of the process. As an example consider a production process that fills bottles with a soft drink that are advertised to contain 16 ounces. The fill X is a measure of the quality of a container. The mean fill μ and the standard deviation σ of the distribution of fills X are typical quality measures of the process. Loss of customers can be associated with μ being too low and unnecessary cost of production when μ is too high. Increases in σ are associated with increases in the proportion of unacceptable over and/or under filled bottles and decreases with quality improvement. It is therefore desirable to control both μ and σ .

The meaning of the process being “in control” is most commonly based on what Shewhart [1] referred to as *natural causes of variability*. We assume that these causes of variability are inherent and can only be removed by redesigning the process. Here we use the word *in control* to mean the state of the process when there are no assignable causes of variability present. When our filling process is in control, we will assume that μ and σ have the values μ_0 and σ_0 , respectively. If assignable causes of variability are present, then $\mu \neq \mu_0$ or $\sigma \neq \sigma_0$ and the process is said to be “out of control.”

Initially, the practitioner must bring the process into a state of statistical control. The Phase I **control chart** is often recommended as an aid to the practitioner for this purpose. The Shewhart Phase I $\bar{X}$ and $\bar{R}$ charts are the most commonly recommended charts to aid the practitioner in bringing the mean μ into a state of statistical control (see Ryan [2] for a discussion of control charts for the mean). The Phase I Shewhart moving range (MR), the sample range (R), and the sample standard deviation (S) charts are recommended for σ . These charts are designed to look at the data collected from the process in retrospect to answer the question “were these data collected from

a process that is in control?” When the process is believed to be in control, it is desirable to monitor the process for a possible change from in control to out of control. The question the practitioner wishes to answer is “has the process changed?” The charts used in the monitoring phase are often referred to as Phase II charts. The Phase II Shewhart MR , R , and S charts are most often used to monitor σ . The R and S (with runs rules) (see Burroughs *et al.* [3], Mitra [4]), the run sum R and S (see Champ and Rigdon [5]), and cumulative sum (**CUSUM**) R and S (see Page [6], Gan [7], Acosta-Mejia [8], and Amin and Wilde [9]), have also been developed to monitor for a change in σ . For a general overview of control charts, see Faltin [10].

Typically, it is recommended that the process standard deviation σ also be controlled when controlling the process mean μ . This is due to the fact that under the normal model the distribution of the plotted statistic for the Shewhart $\bar{X}$ and $\bar{R}$, CUSUM, and **exponentially weighted moving average** (EWMA) charts depend on σ . Thus, if the chart for monitoring μ indicates a possible change in the process this could be due to a change in σ . It is then argued that a chart for controlling for a change σ be examined first. If there is no indication that σ has changed, then any change in the process indicated by the chart for controlling the mean is interpreted as being due to a change in μ . It can be shown that the MR chart is affected not only by changes in σ but also by changes in μ whereas the R and S charts are only affected by changes in σ .

In this article, we will examine the design and use Phase I and II MR and R charts. The charts are designed under the assumption that the quality measurements are independent each having a **normal distribution**. The relative performance of these charts can be examined under the assumption that both μ_0 and σ_0 are known, one is to be estimated, or both are to be estimated.

Moving Range and R Charts

The Shewhart MR and R charts are designed under the assumption that the observed values of X are independent and each has a normal distribution. Also, it is assumed that periodically a random sample of size $n \geq 1$ is taken from the output of the production process. For convenience of discussion, we let $X_{t,j}$

2 Moving Range and R Charts

represent the X measurement on the j th item in sample t . The MR chart is often recommended for the case in which $n = 1$. The common scenario in Phase I is that the practitioner will have available X measurements on the items in m independent random samples each of size n that have been taken periodically from the output of the production process. In our example, the practitioner will have available the measurements $\{X_{t,1}, \dots, X_{t,n}\}$ for $t = 1, \dots, m$.

When $n = 1$, we define the sequence of moving ranges $MR_2, \dots, MR_m$ by

$$MR_t = |X_{t-1,1} - X_{t,1}| \quad (1)$$

It can be shown under our model assumptions that if the process is in control the mean and standard deviation of the distribution MR_t are given, respectively, by $(2/\sqrt{\pi})\sigma_0$ and $\sqrt{2(\pi-2)}/\pi\sigma_0$. If σ_0 were known, the Shewhart 3σ limits upper control limits (UCL) and lower control limits (LCL) for the Phase I Shewhart MR chart are

$$\begin{aligned} LCL &= 0 \quad \text{and} \\ UCL &= \frac{2 + 3\sqrt{2(\pi-2)}}{\sqrt{\pi}}\sigma_0 \approx 3.686\sigma_0 \end{aligned} \quad (2)$$

since $(2 - 3\sqrt{2(\pi-2)})/\sqrt{\pi} \approx -1.429 < 0$. Generally, it is not the case that σ_0 is known. The value of σ_0 is then estimated by the average $\overline{MR}$ of the $m-1$ MR s times an unbiased constant $\sqrt{\pi}/2$, that is, $\overline{MR} = (m-1)^{-1} \sum_{t=2}^m MR_t$. The Shewhart 3σ control limits are then given by

$$\begin{aligned} LCL &= 0 \quad \text{and} \\ UCL &= \frac{2 + 3\sqrt{2(\pi-2)}}{\sqrt{\pi}} \left(\frac{\sqrt{\pi}}{2} \overline{MR} \right) \doteq 3.2665 \overline{MR} \end{aligned} \quad (3)$$

The chart “signals” a potential out-of-control process if $MR_t > UCL$. If a positive LCL is desired or if it is desired to have an overall probability α of at least one of the MR_t ’s indicating a potential out-of-control process when the process is in control, the control limits could be adjusted by selecting the control limits as

$$\begin{aligned} LCL &= (1 - k_L \sqrt{\pi-1}) \overline{MR} = h_L \overline{MR} \quad \text{and} \\ UCL &= (1 + k_U \sqrt{\pi-1}) \overline{MR} = h_U \overline{MR} \end{aligned} \quad (4)$$

where k_L (h_L) and k_U (h_U) are appropriately selected. It is not difficult to show that as the number of samples m increases the probability α the chart signals a potential out-of-control process for fixed chart parameters k_L (h_L) and k_U (h_U) also increases. Some criteria for selecting these chart parameters are such that (a) it is just as likely to observe a value for the plotted statistic less than the LCL as greater than the UCL when the process is in control and (b) it is least likely to observe at least one of the plotted statistics outside the control limits when the process is in control. Using one or both of these criteria for selecting the control limits of the MR chart has not been studied in the literature.

The control limits for the Phase II MR chart are defined in a similar way to those for the Phase I MR chart. The difference is the method for choosing the chart parameters $k_{MR,L}$ ($h_{MR,L}$) and $k_{MR,U}$ ($h_{MR,U}$) and the value of $\overline{MR}$ is based on m independent samples each of size $n = 1$ from a process that is believed to be in control. Typically, the chart parameters of the Phase II MR chart are chosen such that the **average run length** (ARL) of the chart is relatively large when the process is in control and as small as possible when the process is out of control. The run length is the number of samples taken in Phase II until the plotted statistic plots either below LCL or above UCL.

For the case of $n > 1$, often the Phase I Shewhart R chart is recommended as an aid to the practitioner in bringing the process into a state of statistical control. The sample range R is the difference between the maximum and minimum values of the sample. For a discussion of the sample range R see Montgomery [11] and Alwan [12]. Under the normal model, the Phase I Shewhart R has LCL and UCL are defined by

$$\begin{aligned} LCL &= \left(1 - k_{R,L} \frac{d_3}{d_2}\right) \overline{R} \quad \text{and} \\ UCL &= \left(1 + k_{R,U} \frac{d_3}{d_2}\right) \overline{R} \end{aligned} \quad (5)$$

where $\mu_R = d_2\sigma_0$ and $\sigma_R = d_3\sigma_0$. Values of d_2 and d_3 are functions of the sample size n and must be determined numerically. Table 1 gives values for d_2 and d_3 for $n = 2, \dots, 12$. Harter [13], Montgomery [11], and Alwan [12] provide tables of these values.

Often it is recommended that $k_{R,L}$ and $k_{R,U}$ be set to 3 as suggested by Shewhart [1]. As with the MR

Table 1 Constants d_2 and d_3^2

chart, the chart parameters $k_{R,L}$ and $k_{R,U}$ are functions of the number of samples m for a given value of α . Similar to the Phase II Shewhart MR chart, the control limits for the Phase II Shewhart R charts are defined using the same formulas as in Phase I. The differences are that the value of $\bar{R}$ is based on m independent random samples each of size n that are believed to have been taken from a process that is in control. Further, the chart parameters for these charts are usually selected so that the run length distribution when the process is in control has certain properties such as a given in control ARL .

Example

Periodically, from our bottle filling process, we have selected $m = 20$ independent samples each of size $n = 5$. The X fills of these bottles along with the MR for the first sampled value and the range of each sample are recorded in the Table 2.

To illustrate the MR chart, we will consider that we have available only the measurement $x_{t,1}$ taken on the first item in each sample. For these data, the MR chart has $LCL = 0$ and $UCL = 3.2670 \times 0.1974 = 0.6449$ using equation (3). The Phase I MR is displayed in Figure 1.

The control limits for the Phase I R chart are $LCL = 0$ and $= 2.1145 \times 0.1159 = 0.2451$ using equation (5). There is no indication by the Phase I MR chart that these data are from a process that is out of control.

The Phase I R chart is displayed in Figure 2. We see from Figure 2 that the range of sample taken at sampling stage 5 signals a potential out-of-control process. It was also noted that the range of the 17th sample is relative large. Upon further investigation, the practitioner decides that the relatively large values of the range were due to natural causes of variability.

Figure 1 Phase I MR chart with $m = 20$

Figure 3 Phase II MR chart

Figure 2 Phase I R chart with $m = 20, n = 5$

Figure 4 Phase II R chart

Since it is believed that the data collected in Phase I is in control, then the same $3\text{-}\sigma$ limits are used for the Phase II chart. Table 3 contains the data collected in Phase II for the first six samples.

The Phase II MR and R charts are given respectively in Figures 3 and 4.

The Phase II MR chart provides no evidence

that the process has changed. The sample range R_6 of the sixth sample in Phase II signals a potential out-of-control process suggesting to the practitioner that the process should be examined to see it had changed.

Conclusion

In this article, we have discussed the *MR* and *R* charts. These charts are simple to use and interpret. The *MR* chart unlike the *R* chart is affected by changes in both the mean and the standard deviation of the distribution of the quality measurement. Also, it has been shown by Rigdon *et al.* [14] that the Phase II *X* chart performs about as well as the combined Phase II *X* and *MR* chart. We do not recommend using the *MR* chart.

Control Charts for the Standard Deviation

Introduction

All processes, regardless of the degree of sophistication, exhibit variation. This variation may be caused by factors over which we have some degree of control, for example, equipment, materials, methods, personnel, or policies. Alternatively, environmental factors over which we have no control may also contribute to variability. A control chart is a graphical tool that monitors an ongoing process (*see Control Charts, Overview*). The selected quality characteristic is plotted along the vertical axis, whereas the sample or subgroups, selected in order of time, are plotted along the horizontal axis.

A control chart for the standard deviation monitors process variability by plotting the sample standard deviation through an *s-control chart*. The sample standard deviation (s) of a subgroup (or sample) of observations ($X_i, i = 1, 2, \dots, n$) of size n is a measure of their variability around the sample mean and is given by

$$s = \sqrt{\frac{\sum_{i=1}^n (X_i - \bar{X})^2}{n-1}} = \sqrt{\frac{\sum_{i=1}^n X_i^2 - \left(\sum_{i=1}^n X_i\right)^2 / n}{n-1}} \quad (1)$$

where $\bar{X}$ represents the sample mean. Typically, monitoring a process for changes in location and variation is done through simultaneous operation of a chart for the sample mean ($\bar{X}$) and a chart for the standard deviation (s). An alternative is to monitor control charts for the mean ($\bar{X}$) (*see Control Charts for the Mean*) and range (R) (*see Moving Range and R Charts*). However, when the subgroup size is large ($n > 10$), the s chart is preferable to the R chart [1].

Preliminary Considerations

There are two assumptions made in the construction of control charts for the standard deviation. First, the observations are assumed to be independent and identically distributed (i.i.d.). Second, the

observations are assumed to be normally distributed. When the first assumption is not valid, control charts for autocorrelated data could be pursued [2]. These charts will not be discussed in this paper. When the second assumption is not valid, techniques for transforming the observations such that the transformed data meet the assumption of normality, is a possible option. In this context, a common transformation is the **Box–Cox transformation** [3], discussed briefly in a later section. Some preliminary considerations on the manner in which samples are to be selected, the size and frequency of sampling, and the placement of the control limits based on a chosen false alarm rate are necessary prior to the construction of control charts.

Selection of Rational Subgroups

Subgroups are chosen such that the variation within them is only due to common causes. Hence, if special causes are present, subgroups are selected such that they will occur between samples. So, using these concepts, differences *within* samples will be minimized while differences *between* samples will be maximized. Sampling is usually conducted by time order, where observations within a subgroup are homogeneous. Usually, at least 25–30 subgroups of observations must be obtained prior to the construction of control charts.

Sample Size

The sample or subgroup size (n) represents the number of observations in each sample. It is usually greater than or equal to 4. The degree of shift in the process parameter that is expected to take place will influence the choice of the sample size. The larger the sample size, the better the chance of detecting small shifts. Other factors such as the cost of obtaining the information or the cost of shipping a nonconforming item to the customer also influence the choice of sample size.

Frequency of Sampling

Choosing large samples very frequently is the sampling scheme that provides the most information. However, resource constraints may not allow us to do so. Other options include choosing small sample

2 Control Charts for the Standard Deviation

sizes at frequent intervals or large sample sizes at infrequent intervals. The former method is usually chosen. Other factors also influence the frequency of sampling and the sample size. The current state of the process is one factor. For a stable process that is in control, we could get by with sampling at infrequent intervals. The cost of sampling and the loss incurred due to a nonconforming item being passed on to the customer are other factors.

Errors in Decision Making from Control Charts

Decision making from a control chart is analogous to testing a hypothesis. Since sample information is used to make a decision on a population parameter, two types of errors may happen.

False Alarm. A false alarm (known as a *Type I error*) occurs from inferring that a process is out of control when it is actually in control. The probability of a false alarm is denoted by α . Let us suppose that we are using the decision rule of concluding a process to be out of control if the sample statistic plots outside the control limits. Suppose the process is in control. Since the control limits are at a finite distance (usually three standard deviations of the plotted quality characteristic) from the centerline (CL), there is a small chance (given by α) of the sample statistic falling outside the control limits. In such instances, inferring that the process is out of control is erroneous and is known as a *false alarm*. The false alarm can be minimized by having control limits that are wider apart (e.g., four standard deviations of the plotted statistic from the CL). Usually, the control limits are constructed based on a chosen level of significance (α). For a monitored statistic that is normally distributed, a common choice of placement of the control limits is three standard deviations from the CL, yielding a false alarm rate of about 0.0026.

Failure to Signal. A failure to signal (known as a *Type II error*) occurs from inferring that a process is in control when it is really out of control. Suppose our decision rule for concluding that a process is in control is for the observed sample statistic that is being monitored to fall within the control limits. Now suppose that, owing to a change in the vendor, the variation in the quality of the incoming raw material has increased. However, it is possible that

a random sample, chosen after the occurrence of this change, could yield a sample standard deviation that lies within the previously established control limits. Thus, we would erroneously conclude that the process is in control – a failure to signal, the probability of which is denoted by β . The magnitude of the failure to signal error is, however, dependent on the degree of change; in this case the increase in variability. The larger the change, the less the chances of committing a Type II error. The failure to signal error can be minimized by moving the control limits closer to each other (such as two standard deviations of the plotted statistic from the CL), thereby increasing the chance of detection of an out-of-control process. But, doing so will increase the chance of a false alarm. Hence, we note the inverse relationship between the false alarm and failure to signal errors, for a fixed sample size, as the location of the control limits are changed. A measure of performance of control charts is the ability to quickly detect a process change, when the process is out of control. If we denote P_d to be the probability of detection of an out-of-control condition, $P_d = 1 - \beta$. Accordingly, a performance measure is the number of subgroups, on average, to detect an out-of-control signal given by the *average run length* (ARL) where

$$ARL = \frac{1}{P_d} = \frac{1}{(1 - \beta)} \quad (2)$$

Location of Control Limits

Control limits are placed at k standard deviations of the plotted statistic from the CL. Selecting a value for k is influenced by the chosen false alarm rate and by the probability of detecting an out-of-control condition when a process change of a certain magnitude takes place. This involves a trade-off between the false alarm and failure to signal errors. Usually, k is selected based on a chosen level of the false alarm rate (α), where importance is placed on limiting the probability of a false alarm. Assuming normality of distribution of the characteristic, k is typically chosen to be 3, justifying the name “ 3σ ” limits, for which the probability of a false alarm (α) is limited to 0.0026. In this chapter, we will discuss and present only “ 3σ ” control limits, even though, in general, k could take on other values.

Rules for Identifying Out-of-Control Conditions

A major objective of using control charts is to determine when a process is out of control so that necessary remedial actions may be taken. A systematic or nonrandom pattern of the plotted values suggests an out-of-control condition. Some commonly used rules are as follows:

1. A single-point plots outside the control limits.
2. Two out of three consecutive points fall outside the “ 2σ ” warning limits on the same side of the CL.
3. Four out of five consecutive points fall outside the “ 1σ ” limit on the same side of the CL.
4. Nine or more consecutive points fall to one side of the CL.

The first rule is the one that is routinely used. As more rules are used simultaneously, the chance of a false alarm increases. Suppose that the number of independent rules used is p , and let α_i be the probability of a false alarm of rule i . The *overall false alarm rate* is given by

$$\alpha = 1 - \prod_{i=1}^p (1 - \alpha_i) \quad (3)$$

Construction of Standard Deviation Control Charts

For a normally distributed quality characteristic with a *population standard deviation* denoted by σ , the mean and the standard deviation of the sample standard deviation [2] are given by

$$E(s) = c_4 \sigma \quad (4)$$

$$\sigma_s = \sigma \sqrt{1 - c_4^2} \quad (5)$$

respectively, where c_4 is a factor that depends on the sample size and is given by

$$c_4 = \left[\frac{2}{(n-1)} \right]^{1/2} \frac{\Gamma(n/2)}{\Gamma[(n-1)/2]} \quad (6)$$

The expression $\Gamma(\cdot)$ represents the gamma function.

No Given Standards

The CL of a standard deviation chart is

$$CL_s = \bar{s} = \frac{\sum_{i=1}^g s_i}{g} \quad (7)$$

where g is the number of samples and s_i is the standard deviation of the i th sample. The upper control limit is

$$UCL_s = \bar{s} + 3\sigma_s = \bar{s} + 3\sigma \sqrt{1 - c_4^2} \quad (8)$$

In accordance with equation (4), an estimate of the population standard deviation σ is

$$\hat{\sigma} = \frac{\bar{s}}{c_4} \quad (9)$$

Substituting this estimate of $\hat{\sigma}$ in the preceding expression yields

$$UCL_s = \bar{s} + \frac{3\bar{s}\sqrt{1 - c_4^2}}{c_4} = B_4 \bar{s} \quad (10)$$

where $B_4 = 1 + 3 \frac{\sqrt{1 - c_4^2}}{c_4}$. Similarly,

$$LCL_s = \bar{s} - \frac{3\bar{s}\sqrt{1 - c_4^2}}{c_4} = B_3 \bar{s} \quad (11)$$

where $B_3 = \max \left[0, 1 - 3\sqrt{(1 - c_4^2)}/c_4 \right]$. Thus, the 3σ control limits are

$$UCL_s = B_4 \bar{s} \quad (12)$$

$$LCL_s = B_3 \bar{s} \quad (13)$$

The CL of the chart for the mean $\bar{X}$ is given by

$$CL_{\bar{X}} = \bar{\bar{X}} = \frac{\sum_{i=1}^g \bar{X}_i}{g} \quad (14)$$

The control limits on the $\bar{X}$ chart are

$$\bar{\bar{X}} \pm 3\sigma_{\bar{X}} = \bar{\bar{X}} \pm \frac{3\sigma}{\sqrt{n}} \quad (15)$$

4 Control Charts for the Standard Deviation

where $\bar{\bar{X}}$ is the CL and represents the grand mean (or mean of the sample means). Using equation (9) to obtain $\hat{\sigma}$, we find the control limits to be

$$UCL_{\bar{X}} = \bar{\bar{X}} + \frac{3\bar{s}}{c_4\sqrt{n}} = \bar{\bar{X}} + A_3\bar{s} \quad (16)$$

$$LCL_{\bar{X}} = \bar{\bar{X}} - \frac{3\bar{s}}{c_4\sqrt{n}} = \bar{\bar{X}} + A_3\bar{s} \quad (17)$$

where $A_3 = 3/(c_4\sqrt{n})$.

The above-constructed limits are known as *trial control limits*. The values of the sample mean ($\bar{X}_i$) and sample standard deviation (s_i) are plotted on the respective control charts along with the CL and the trial control limits. On the basis of the chosen rules for out-of-control conditions, we determine if any points are out of control on the s chart or the $\bar{X}$ chart. The s chart is looked at first. Only if it is in control should the $\bar{X}$ chart be developed, since the standard deviation of $\bar{X}$ is dependent on $\bar{s}$. If the s chart is not in control, any estimate of the standard deviation of $\bar{X}$ will be unreliable, which will create unreliable control limits for $\bar{X}$ [1.]

When there are out-of-control points, the investigator tries to identify special causes associated with them, if any. The pattern of the plot may indicate possible special causes and, further, the corresponding remedial actions. For example, a sequence of six or more consecutive points that are increasing on an s chart may indicate a progressive increase in the variability of the process. On investigation, a possible cause could be the gradual deterioration in the raw material quality due to the cumulative effects of humidity over time. After identification of remedial actions to eliminate the special causes, the out-of-control points are deleted, and the revised CL and control limits are calculated. This cycle of obtaining process information, determining trial limits, finding out-of-control points, identifying and correcting special causes, and determining revised control limits continues. The revised control limits serve as trial control limits for the immediate future until the limits are revised again. Such an ongoing process is a critical component of continuous improvement.

Given Standard

If a target standard deviation is specified as σ_0 , the CL of the s chart is found by using equation (4) as

$$CL_s = c_4\sigma_0 \quad (18)$$

The upper control limit (UCL) for the s chart is found by using equation (5)

$$\begin{aligned} UCL_s &= c_4\sigma_0 + 3\sigma_s = c_4\sigma_0 + 3\sigma_0\sqrt{1 - c_4^2} \\ &= \left(c_4 + 3\sqrt{1 - c_4^2}\right)\sigma_0 = B_6\sigma_0 \end{aligned} \quad (19)$$

where $B_6 = c_4 + 3\sqrt{1 - c_4^2}$. Similarly, the lower control limit (LCL) for the s chart is

$$LCL_s = \left(c_4 - 3\sqrt{1 - c_4^2}\right)\sigma_0 = B_5\sigma_0 \quad (20)$$

where $B_5 = \max\left[0, c_4 - 3\sqrt{1 - c_4^2}\right]$. Thus, the control limits for the s chart are

$$UCL_s = B_6\sigma_0 \quad (21)$$

$$LCL_s = B_5\sigma_0 \quad (22)$$

If a target value for the mean is specified as $\bar{X}_0$, then the CL on the $\bar{X}$ chart is given by

$$CL_{\bar{X}} = \bar{X}_0 \quad (23)$$

Equations for the control limits on the $\bar{X}$ chart are given by

$$UCL_{\bar{X}} = \bar{X}_0 + A\sigma_0 \quad (24)$$

$$LCL_{\bar{X}} = \bar{X}_0 - A\sigma_0 \quad (25)$$

where $A = 3/\sqrt{n}$.

Interpretations of the s Chart

Note that the LCL on the standard deviation control chart cannot be negative. Hence, using “3 σ ” control limits, if the LCL is calculated to be negative, it is converted to zero.

When the LCL on the s chart is positive and an observation plots below it, the process is considered to be out of control. However, in this case it is a desirable condition that indicates that the variability in the process is unusually small. When the corresponding special cause is identified, management should make an effort to move process conditions toward this situation so that the reduced process variability may be sustained in the future.

Related Topics

Estimating Process Standard Deviation

A point of interest from the standard deviation control chart is to obtain a suitable estimate of the process standard deviation (σ). There are three common estimates of σ .

1. One approach is to base the estimation on the average range of the samples. Let R_i denote the range of observations for sample i , $i = 1, 2, \dots, g$. The average range is given by

$$\bar{R} = \frac{\sum_{i=1}^g R_i}{g} \quad (26)$$

When sampling from a normal population, the distribution of the relative range (W), given by R/σ , is dependent on the sample size, n . The mean of W is represented by a factor d_2 [1]. Hence, an estimate of σ is obtained from

$$\hat{\sigma}_1 = \frac{\bar{R}}{d_2} \quad (27)$$

2. A second estimate of σ is found from the average of the standard deviations of the individual samples, where the sample size of each is n . This estimator is given by equation (9):
3. A third estimate of σ is based on the pooled estimate of the sample variances. If the sample size is constant for each sample and denoted by n , the pooled estimate is given by

$$s_p = \left[\frac{1}{g} \sum_{i=1}^g s_i^2 \right]^{1/2} \quad (28)$$

An unbiased estimator of the process standard deviation is obtained as

$$\hat{\sigma}_p = \frac{s_p}{c_4} \quad (29)$$

When the subgroup sizes vary from subgroup to subgroup, a pooled estimate of the process standard deviation is found as

$$s_p^* = \left[\frac{\sum_{i=1}^g (n_i - 1) s_i^2}{\sum_{i=1}^g n_i - g} \right]^{1/2} \quad (30)$$

Correspondingly, an unbiased estimator of the process standard deviation is given by

$$\hat{\sigma}_p^* = \frac{s_p^*}{c_4} \quad (31)$$

where c_4 is calculated using equation (6) with an equivalent sample size of $(\sum n_i - g + 1)$. This pooled estimate, s_p^* , may be used to construct the CL and control limits for the s chart when the subgroup size varies. The procedure is similar to that outlined before (where $\bar{s}$ is replaced by s_p^*). However, the control limits are not constant, but change from subgroup to subgroup.

4. One major objective of the control chart is to determine out-of-control conditions quickly, when the process is out of control. On the basis of simulation results that determine the average and the standard deviation of the run length, for detection of out-of-control conditions [4], the pooled estimate (s_p) is found to be desirable, relative to the other estimates.

Estimating Process Capability

The capability of a process is its ability to meet customer specifications. Capability can be estimated only when a process is in control, since only then is the output from a process stable and predictable. Hence, control charts serve a purpose in **estimating process capability**.

Typical capability measures involve computations that compare the specification spread to the process spread. Since the process spread is influenced by the estimated process standard deviation, the type of estimate used has an impact on the estimated capability. For short-term capability measures, estimates of the process standard deviation given by equations (9), (27), (29), or (31), may be used. These estimates are measures of the within-subgroup variation.

For long-term capability measures, a measure of the overall process variability is given by

$$s_{LT} = \frac{\sum_{i=1}^g \sum_{j=1}^{n_i} (X_{ij} - \bar{\bar{X}})^2}{(\sum n_i) - 1} \quad (32)$$

where $\bar{\bar{X}}$ represents the grand average of all the observations, once the process is in control.

6 Control Charts for the Standard Deviation

Table 1 Copper deposition thickness (in microns) in printed circuit boards

Subgroup number	Observations					Subgroup number	Observations				
1	43.47	38.43	44.41	36.48	31.42	14	29.58	39.86	34.84	21.77	36.63
2	37.25	40.65	46.40	22.73	30.74	15	23.88	47.92	22.71	21.98	28.76
3	19.78	19.13	20.31	26.48	33.69	16	21.76	35.77	34.98	33.36	33.20
4	22.39	31.54	24.40	20.63	31.64	17	17.86	26.15	56.48	15.83	38.37
5	36.61	23.31	27.93	25.45	19.65	18	35.18	30.73	30.43	30.31	30.47
6	22.48	32.74	31.69	38.88	37.09	19	20.67	34.47	35.56	19.35	27.21
7	29.78	34.41	26.07	19.56	10.01	20	28.56	41.36	28.67	33.61	39.63
8	43.38	22.64	38.32	31.76	26.13	21	35.63	25.18	39.60	42.70	9.53
9	24.86	27.48	31.30	25.21	37.95	22	35.82	23.28	27.27	27.38	30.26
10	29.19	26.51	35.05	36.67	36.53	23	23.49	29.29	30.49	21.35	29.14
11	34.61	21.21	24.66	36.58	35.70	24	38.66	49.59	24.46	32.21	21.05
12	55.44	38.68	34.74	42.53	32.18	25	46.43	26.89	41.78	25.87	29.23
13	24.54	40.76	43.19	34.67	26.02						

An unbiased estimate of the overall process standard deviation is obtained from

$$\hat{\sigma}_{LT} = \frac{s_{LT}}{c_4} \quad (33)$$

where c_4 is calculated using equation (6) with an equivalent sample size of $(\sum n_i - g + 1)$.

Nonnormality of Distribution

When the distribution of the quality characteristic does not follow a **normal distribution**, one approach is to transform the data. A form of power transformation, where the transformed variable follows normality, is the Box–Cox transformation [3, 5] (*see Box and Cox Transformation*). It is given by

$$\begin{aligned} X_T &= X^\lambda, \lambda \neq 0 \\ &= \ell n(\lambda), \text{ when } \lambda = 0 \end{aligned} \quad (34)$$

The Box–Cox method estimates a value for λ which minimizes the standard deviation of the standardized transformed variable [3, 5].

Another approach is to use a distribution-free or nonparametric procedure for constructing control charts, when the quality characteristic could be from any general distribution (*see Control Charts, Nonparametric*). While this approach vastly expands the scope of application of control charts, without any restriction on the distributional form of the characteristic, it may suffer from having a smaller power to detect process changes relative to parametric control charts.

Example

In the manufacture of printed circuit boards (PCBs), an electroplating process is utilized where the circuitry is plated with copper. The copper deposition rates are found to be varying quite a bit and are influenced by factors such as plating time, bath temperature, current density, and bath concentration. Table 1 shows the copper deposition thickness (in microns) for 25 randomly chosen groups from the process. Each subgroup consists of five observations, randomly selected in close proximity in time. The specifications of thickness are 25–35 μm .

The control chart constants for construction of the 3σ control charts for the s chart may be calculated using previously defined equations. For example, using equation (6), we get

$$c_4 = \left[\frac{2}{(5-1)} \right]^{1/2} \frac{\Gamma(5/2)}{\Gamma[(5-1)/2]} = 0.9400 \quad (35)$$

Consequently, the control chart factor for obtaining the UCL for the s chart is obtained as

$$B_4 = 1 + 3 \frac{\sqrt{1 - c_4^2}}{c_4} = 1 + 3 \frac{\sqrt{1 - 0.94^2}}{0.94} = 2.089 \quad (36)$$

Similarly, the control chart factor for obtaining the LCL for the s chart is found to be

$$\begin{aligned} B_3 &= \max \left[0, 1 - 3 \frac{\sqrt{1 - c_4^2}}{c_4} \right] \\ &= \max[0, -0.089] = 0 \end{aligned} \quad (37)$$

Figure 1 Control charts for the mean and standard deviation using trial control limits

For the $\bar{X}$ chart, the control chart factor for the control limits, as given by equation (16), is obtained as

$$A_3 = \frac{3}{(c_4\sqrt{n})} = \frac{3}{(0.9400\sqrt{5})} = 1.427 \quad (38)$$

We demonstrate construction of control charts for the mean ($\bar{X}$) and standard deviation (s) using a statistical software package, Minitab [6], that is widely used in practice. In order to use Minitab, the data must be input as a worksheet, where the columns are treated as variables and the rows represent the selected samples or subgroups. Here, each subgroup is input in a single row, with the five observations being input in columns 1 through 5 (C1–C5).

Since a prior estimate of the process mean or standard deviation is not specified, we use the sample data to estimate these parameters and accordingly construct control charts. The following commands are executed: *Stat > Control Charts > Variable Charts for Subgroups > X bar – S*. Indicate that the observations for a subgroup are in one row of columns. Input the column numbers, here C1–C5, since the worksheet contains the observations in the first five columns. Click on *X bar – S Options*, select *Estimate*, and under *Method for estimating standard*

deviation, choose either *S bar* or *Pooled standard deviation* (the default option). The *S bar* option uses the version given by equation (7), while the latter uses the versions given by equations (28) or (30). In each case, Minitab allows us to select “Use unbiasing constant”, which is the default option. Thus, the process standard deviation is estimated either by equation (9), or by equations (29) or (31), depending on the selection. Under the *Tests for special causes* option, we select the first rule, which is a single point outside the “ 3σ ” control limits. Click *OK*.

Figure 1 shows the control charts for the mean and standard deviation using trial control limits. On the $\bar{X}$ chart, the CL is 31.12, while the control limits are (42.21, 20.04). On the s chart, the CL is 7.76, while the control limits are (16.22, 0). Using the specified rule for detecting out-of-control conditions, we find that on the s chart, the sample standard deviation for subgroup number 17 is unusually high and falls above the UCL. This calls for investigation of possible special causes associated with this subgroup. On looking into the process, it is deemed that major changes in the bath concentration occurred. Accordingly, remedial measures were put into place that would indicate whenever the bath concentration is outside certain specified bounds.

Figure 2 Control charts for the mean and standard deviation using revised control limits

Subgroup number 17 is now deleted, and revised control charts are constructed using the remaining subgroups. Figure 2 shows the revised control charts for the mean and standard deviation. Using the specified rule for detection of out-of-control conditions, none is found to be out of control. Now that we have a process that is in control and stable, we can estimate the process standard deviation. Since the revised CL on the s chart is 7.24, and the constant (c_4) from equation (6) using a subgroup size of 5 is 0.9400, an estimate of the process standard deviation using equation (29) is $7.24/0.94 = 7.702$. An estimate of the process average, from the $\bar{X}$ chart, is observed to be 31.13. These values may be used to determine process capability, the ability of the process, to meet the required specifications of 25–35 μm .

Conclusions

The standard deviation control chart is a very handy tool to monitor process variability as measured by its standard deviation. While a control chart for the range is another tool for monitoring process variation, the standard deviation chart is preferred to the range chart for subgroups of large size.

Process changes may take place either in the location of a process, variation of a process, or both. Control charts for the mean are used to monitor changes in process location. Hence, to monitor the stability of a process, either an $\bar{X}$ and s chart, or an $\bar{X}$ and R chart are used in conjunction with each other.

Estimation of the process standard deviation is a desired outcome of process control through an s chart. Such an estimate helps us assess process capability, which is the ability of the process to meet set specifications. Further, computation of proportion nonconforming of the product is possible once an estimate of the process mean and process standard deviation are available.

Control Charts for Attributes

Introduction

Control charts for attributes are useful when the quality characteristics are classifications rather than measures of a continuous trait. For example, when an item is to be classified as conforming to quality standards or nonconforming, attribute control charts are often used. The p -chart is an attribute chart based on the binomial model and is used to monitor the proportion of nonconforming items in a sample. Another type of attribute chart, the c -chart, is based on the Poisson model and is useful when a nonconforming item has multiple nonconformities or defects. A c -chart can be used to monitor the number of occurrences of defects over some interval of time or area rather than the proportion of nonconforming items in a sample. For example, one might monitor the number of surface blemishes per 20 sq ft of surface area of a finished product.

p -Chart

The proportion of nonconforming items in the t^{th} sample or subgroup is defined by

$$\hat{p}_t = \frac{X_t}{n} \quad (1)$$

where X_t is the number of nonconforming items in the subgroup and n is the total number of items in the sample. To establish the control limits, m subgroups of size n are gathered when the process is in-control and the number of nonconforming items is recorded for each subgroup. The average of the proportion of nonconforming items in the initial subgroups is defined as

$$\bar{p} = \frac{\sum_{i=1}^m X_i}{mn} \quad (2)$$

The lower control limit (LCL), center line (CL), and upper control limit (UCL) of the p -chart are given by

$$LCL = \bar{p} - 3\sqrt{\frac{\bar{p}(1-\bar{p})}{n}} \quad (3)$$

$$CL = \bar{p} \quad (4)$$

$$UCL = \bar{p} + 3\sqrt{\frac{\bar{p}(1-\bar{p})}{n}} \quad (5)$$

These limits are considered trial control limits. The subgroup proportions from the initial sample, $\hat{p}_1, \hat{p}_2, \dots, \hat{p}_m$, should be compared to the control limits, and if the values fall outside the limits, those subgroups should be investigated for assignable causes to an out-of-control situation. If assignable causes are found, these subgroups should be excluded from the calculation of $\bar{p}$, and new limits should be determined. It is often recommended that $m > 30$ subgroups be used to establish the chart. Once the chart is established, samples of size n are continually observed, and the proportion of nonconforming items in the subgroup, $\hat{p}_t$, is plotted.

Example of p -Chart

A manufacturer of cordless telephones tracks the proportion of nonconforming units produced. At the end of each of the three daily shifts, $n = 50$ phones are sampled from the production run. After the first 11 days, data is gathered from $m = 33$ subgroups of size $n = 50$. This information is given in Table 1.

The CL is given by $\bar{p} = 0.1085$; thus the trial control limits are

$$\begin{aligned} LCL &= \bar{p} - 3\sqrt{\frac{\bar{p}(1-\bar{p})}{n}} = 0.1085 - 0.1320 \\ &= -0.0235 \end{aligned} \quad (6)$$

and

$$\begin{aligned} UCL &= \bar{p} + 3\sqrt{\frac{\bar{p}(1-\bar{p})}{n}} = 0.1085 + 0.1320 \\ &= 0.2405 \end{aligned} \quad (7)$$

Because the LCL is computed to be a negative value, it will be set to zero on the chart.

Three consecutive subgroups (13, 14, and 15) are above the UCL suggesting excessive nonconforming items. It is discovered that these values occurred during a holiday when the production line was staffed with inexperienced workers. The three subgroups are removed from the calculation of the control limits,

2 Control Charts for Attributes

Table 1 Example data

Subgroup number, i	Number	
	Nonconforming units, X_i	Fraction nonconforming, p_i
1	8	0.16
2	3	0.06
3	1	0.02
4	5	0.10
5	3	0.06
6	3	0.06
7	6	0.12
8	3	0.06
9	4	0.08
10	5	0.10
11	3	0.06
12	5	0.10
13	13	0.26
14	15	0.30
15	17	0.34
16	2	0.04
17	7	0.14
18	4	0.08
19	1	0.02
20	6	0.12
21	1	0.02
22	5	0.10
23	6	0.12
24	6	0.12
25	8	0.16
26	3	0.06
27	5	0.10
28	7	0.14
29	3	0.06
30	3	0.06
31	7	0.14
32	5	0.10
33	6	0.12
179		0.1085

and the revised CL is found to be $\bar{p} = 0.0893$. The revised control limits are

$$LCL = \bar{p} - 3\sqrt{\frac{\bar{p}(1-\bar{p})}{n}} = 0.0893 - 0.1210 = -0.0316 \quad (8)$$

and

$$UCL = \bar{p} + 3\sqrt{\frac{\bar{p}(1-\bar{p})}{n}} = 0.0893 + 0.1210 = 0.2103 \quad (9)$$

Once again, the LCL is set to zero. The revised control chart is pictured in Figure 1. This chart contains 21 additional plotted subgroup values.

The limits of the chart in Figure 1 are based on 30 of the 33 initial subgroups of data. Following subgroup 33, a workforce retraining program was instituted. The final 21 subgroups are plotted to monitor the process improvement following the retraining. There appears to be a downward shift in the fraction of nonconforming items as a result of the training.

***c*-Chart**

The statistic plotted on a *c*-chart is the count of the number of nonconformities or defects over a specified unit. The specified unit may be a single item, a sample of multiple items, or a fixed time interval. The LCL, CL, and UCL of a *c*-chart are given by

$$LCL = \bar{c} - 3\sqrt{\bar{c}} \quad (10)$$

$$CL = \bar{c} \quad (11)$$

$$UCL = \bar{c} + 3\sqrt{\bar{c}} \quad (12)$$

where $\bar{c}$ is the average number of nonconformities observed in an initial in-control sample of m inspection units. Again, the limits are considered to be trial limits. If any of the initial counts plot outside of the limits and assignable causes are found, these units should be eliminated from the calculation of the control limits. Once the limits are established, future counts are plotted to monitor the process or product quality.

Other Attribute Charts

Other common attribute charts include the *np*-chart, which is used to monitor the number of nonconforming items and, like the *p*-chart, is based on the binomial model. The *u*-chart, similar to the *c*-chart, is based on the Poisson model, and can be used to monitor for the rate of occurrence of nonconformities. The *u*-chart is useful when the specified unit or window of opportunity for nonconformities varies over time. Additionally the *p*-chart can be adapted

Figure 1 Revised control limits

for use when the subgroup size is not constant over time.

Adaptive sampling methods (*see Variable Sampling Rate Control Charts*), cumulative sum (CUSUM) (*see Cumulative Sum (CUSUM) Chart*), and exponentially weighted moving average (EWMA) (*see Exponentially Weighted Moving Average (EWMA) Control Chart*) charts have been recommended to improve the sensitivity of control charts for attributes. Ryan and Schwertman [1] discuss methods for finding optimal control limits for attribute charts. Woodall [2] provides a thorough bibliography of articles related to attribute control charts.

Merits and Limitations of Attribute Charts

It is commonly believed that variable control charts such as the $\bar{X}/R$ chart (*see Control Charts for the Mean; Moving Range and R Charts*) are preferred over attribute control charts. The benefits of variable control charts over attribute charts include the ability to separately monitor the process mean and variance,

the ability to monitor specific quality characteristics rather than defective products or nonconformities, and the ability to indicate process problems prior to a result of defective products. Variable control charts also tend to provide more information regarding potential out-of-control conditions within the process. However, attribute control charts are useful when the process under study is a complex assembly or service operation where several types of problems might occur simultaneously. Several characteristics can be summarized into a single easy-to-understand chart, which makes attribute charts particularly useful for historical studies and presentations to management. Additionally, when measurement data cannot be obtained, statistical process control may still be possible with attribute charts.

Multivariate Control Charts Overview

Introduction

Multivariate statistical process control (MSPC) is used to simultaneously monitor multiple measurements from a process. Similar to the case for a single variable, the objective is to detect assignable causes of variation. Multiple measurements are quite common in modern processes. Multiple process variables might be measured such as temperatures, pressures, material properties, concentrations, flow rates, valve settings, revolutions, voltages, and so on. Multiple measurements might also be derived from the product (such as numerous physical dimensions, thickness, surface finish, gloss, uniformity, and so on). In general cases there may be very different units of measurement. In special cases of MSPC, there might be multiple measurements in the same units, such as thickness measurements at several sites on a surface, or lengths of multiple vanes on a single part, or an absorption spectrum for a range of wavelengths of light. Common units often occur in **multiple stream processes**, and [1] provides a summary. Profile measurements often provide additional examples (*see Profile Monitoring*). Multiple measurements allow one to consider a number of interesting strategies to monitor the process.

In addition to the cases mentioned previously, multiple measurements arise in other ways. A summary statistic might be used to combine data. For example, the mean thickness from several sites on a semiconductor wafer can be used to summarize multiple measurements to one. Consequently, the summary can be monitored with a **control chart** for a single variable. If some sites were near the center of the wafer and some were near the edge, one might also consider additional summaries such as the mean thickness at the edge minus the mean at the center. This leads to another summary, and another variable to be monitored. Consequently, multivariate data occurs again, although the number of metrics might be reduced from every site to fewer summary scores. Still, with more than one summary score to monitor, the application is again within the area of MSPC.

In a batch process one might monitor the temperature over time as the batch starts and then ends. This becomes more interesting when one considers that batches should also be monitored over time. From the view of the process, each batch provides potentially a large number of temperature measurements. Furthermore, a single temperature is probably supplemented with other temperature sensors, and other variable measurements. There may be several variables measured over time for every batch, and then the batches are monitored in sequence. Consequently, a number of alternative designs are feasible for a process monitor, but clearly multiple measurements are involved (*see Control Charts for Batch Processes*).

In yet another application for MSPC, the (rpm) revolutions per minute of a pump is often monitored with the pressure change across the pump. One expects an increase in rpm to correspond to an increased pressure differential. Although there are two variables, (the rpm might be considered an input variable and the pressure change an output), the variables do not have the same symmetric relationship that occurs with measurements from different sites on a wafer. Consequently, the nature of a strategy to monitor this data might incorporate the input–output structure. Still, multiple measurements are involved. A regression-type approach for MSPC has been applied, with and without, a direct cause and effect relationship among the variables (*see Regression Control Charts*).

As a transaction progresses through a business process, intermediate cycle times become available. The set of cycle times provides multiple measurements for each transaction.

Advantages of MSPC

With multiple measurements, each can be monitored in its own control chart. However, this has two disadvantages. One is that it is difficult to control the number of false alarms. An out-of-control action plan (OCAP) needs to begin whenever any control chart for a process signals. With multiple measurements and a correspondingly large number of control charts, there is much greater opportunity for false alarms. If the measurements plotted on each chart are independent, the increase in false alarms can be computed from basic probability. However, multiple

2 Multivariate Control Charts Overview

Figure 1 A scatter plot of two correlated measurements x_1 and x_2 displays an elliptical shape, but one point in the lower right does not conform to the pattern

measurements are often correlated and this makes the calculation more difficult. In any case, the control limits on each chart need to be widened to control the false alarms and this may degrade the detection of assignable causes.

The second disadvantage of separate control charts is more important. There are often important relationships between variables that should be considered for MSPC. Multiple measurements from a process are often redundant, and correlated, and reflect data from many fewer true process states. Figure 1 provides a scatter plot of two measurements from a process. Notice the data is not randomly dispersed in the plot. Instead, the data clusters into an ellipse shape (except for a single point denoted as x_0). This is expected from measurements that are correlated. In Figure 1, the single point x_0 is clearly seen as unusual. Figure 2 shows that neither of the separate control charts for x_1 and x_2 indicate any problems. If x_1 and x_2 are measurements from two sites on a wafer, there is an unusual relationship observed for the wafer corresponding to point x_0 . As another example, if x_1 is the rpm of a pump and x_2 is the pressure differential, point x_0 suggests a broken blade (increased rpm without a corresponding pressure change). An unusual data point potentially signifies that an **assignable cause** is present. Therefore, MSPC has detected unusual process results that neither separate control chart can identify.

Similar relationships occur between variables in higher dimensions. Although simple graphics cannot be viewed, the shape can be confirmed from numerical calculations. Consequently, MSPC can be used to monitor for unusual points in multiple dimensions and this provides a powerful methodology. Data points that are distant from the typical, in-control data in multiple dimensions signal potential assignable causes.

The data points tend to form an elliptical shape, and the major axis of the ellipse can be described by a line. The data points cluster along this line due to the **correlation**. In higher dimensions, data often clusters into lower-dimensional subspaces such as a plane in three dimensions (or a hyperplane in higher dimensions). An MSPC strategy can identify these subspaces and build monitors that focus on the subspace or deviations from the subspace.

Structure of the Data

MSPC has traditionally assumed that the measurements are available in the form of a table of numbers. Each row represents a time instant, and the numbers in the row are the measurements obtained from the process at that time (temperatures, pressures, etc.). Consequently, categorical measurements such as *{poor, average, good}* need to be quantified. However, additional work might be needed to acquire

(a)

(b)

Figure 2 Individual control charts for each variable x_1 and x_2 do not show any assignable causes. Can you identify the control chart points that correspond to the point in the lower right of Figure 1?

this convenient table. For example, the cycle times in the business process described previously will require some work to fit this table, and several alternatives might be useful (based on the objectives of the analysis). Similarly, the final quality measurement of a

product produced now is not dependent on the particle size distribution of the raw material now, but on an earlier, tracked lot of raw material that was used for the current product. Furthermore, many products might have been produced from the same lot of raw

material. Laboratory measurements might be taken from only a sample of products. This leads to different frequencies and phases of measurements that probably influence how to construct the table. Also, a particle size distribution may need to be summarized to a few numbers. Consequently, the traditional table might require substantial work as material flows from a start to an end of a process and measurements are derived in between. The batch process described previously presents additional challenges with time of batch, measurement time within the batch, and multiple variables. The design alternatives are driven by the objectives of the analysis.

Also, the numbers in the table are assumed to not be missing. If so, an interpolation or estimation might be needed. The statistical literature has considered several options for measurement **imputation**. The alternative is to eliminate rows that are not complete. However, with different frequencies of measurement this is not an attractive option. Large numbers of rows might be forced to be discarded. More modern, computationally intensive alternatives exist, but these are beyond the scope of this article.

Assignable Causes

MSPC has focused on control procedures to monitor process parameters. The parameters are the natural extensions from the case of a single variable. There is a mean μ_j and variance σ_j^2 for every variable X_j , say for $j = 1, 2, \dots, p$. Furthermore, MSPC considers the collection of covariances σ_{jk} between variables X_j and X_k . Consequently, there are control charts to monitor means the μ_j 's and those for the variances and covariances.

Usually the variances and covariances are organized into a table called the **covariance matrix** as

$$\begin{pmatrix} \sigma_1^2 & \sigma_{12} & \dots & \sigma_{1p} \\ \sigma_{21} & \sigma_2^2 & \dots & \sigma_{2p} \\ \dots & \dots & \dots & \dots \\ \sigma_{p1} & \sigma_{p2} & \dots & \sigma_p^2 \end{pmatrix}$$

and the objective is to monitor for an assignable cause that changes any one of these parameters. The multiple parameters dramatically increase the challenge from the case of a simple range chart. The article **Multivariate Charts for Variability** presents MSPC for such a covariance matrix.

The means of the variables are also assembled into a mean vector,

$$\mu = (\mu_1, \mu_2, \dots, \mu_p)$$

and monitors for a change to *any* element of this vector are of substantial interest. As shown in the previous figures an integrated strategy that uses the data from all variables can detect assignable causes not visible to separate control charts.

MSPC has focused on a change to any or all elements of the mean vector. Such an omnibus strategy can simultaneously monitor the means of all process variables. However, the chapters here for MSPC show that the omnibus strategy suffers as the number of process variables (denoted p) increases. Consequently, there is also interest in monitors for more restricted assignable causes.

As mentioned previously, high-dimensional data often cluster into lower-dimensional subspaces because of the correlations between the variables. Consequently, assignable causes that preserve the correlation are expected to shift the mean vector within this subspace. Alternatively, an assignable cause that specifically changes the relationships between the variables, might be expected to shift the mean vector from the subspace. When a pump blade breaks the relation between rpm and pressure differential is no longer valid. In either case, these are restrictions on the mean vector under an assignable cause, and such knowledge can be used to improve the performance of MSPC. Principal components analysis (PCA) has been widely used in this context. Much of the PCA work was summarized by Jackson [2], and further development of dimensional reduction currently continues. A more general subspace was considered by Runger [3]. For related examples, *see* **Control Charts for Batch Processes**.

One-sided control charts are common for a single variable. Therefore, the same motivation applies to multivariate data. Interest might be only in an increase in the mean of one or more variables. It is surprisingly more difficult to accommodate such simple information into a multivariate control chart, but solutions have been developed [4].

Nonparametric approaches have also been applied to the MSPC problem. For an introduction, *see* **Control Charts, Nonparametric**. Nonparametric density estimates and monitors to detect changes in these have been considered. Computationally intensive alternatives such as neural networks (*see* **Neural**

Networks: Construction and Evaluation) and other methods have also been considered, but these extensions are beyond the scope of this discussion.

Multivariate Control Charts

Common control charts for MSPC parallel the charts for a single variable. Consequently, there are multivariate extensions to Shewhart, **exponentially weighted moving average** (EWMA), and cumulative sum (CUSUM) control charts. The chapters **Hotelling's T^2 Chart**, **Multivariate Exponentially Weighted Moving Average (MEWMA) Control Chart**, and **Multivariate Cumulative Sum (CUSUM) Chart** describe each of these charts in more detail. The charts apply to a data row, or vector, of arbitrary length p . Consequently, the charts can be applied either before or after a dimensional reduction is used with the data. Suitably modified charts can monitor the mean vector or covariance matrix of the process. The charts are developed with a phase I and phase II strategy identical to the one used for a single variable (see **Control Charts, Overview**). Trial control limits might need to be modified on the basis of assignable causes. Rational subgrouping principles apply, although individual observations are typically used.

MSPC charts are designed for numerical data, and for processes that are characterized in terms of the mean vector and covariance matrix (called *second-order moments*). Although the charts are robust to nonnormality, the process measurements are expected to form elliptical regions, with greater density at the centers of the ellipse. The distance from an observed data vector x_i (or a appropriate sum or average) to the historical process mean vector μ is an important component of these charts. Rather than Euclidean distance, Mahalanobis distance is used

$$(x_i - \mu)' \Sigma^{-1} (x_i - \mu)$$

where Σ denoted the covariance matrix of the variables. Of course, the unknown parameters in the distance calculation need to be estimated in the phase I analysis. From basic algebra it can be shown that points with equal Mahalanobis distance from μ fall on the surface of an ellipse centered at μ . Consequently, a point with large Mahalanobis distance does not follow the expected elliptical pattern as described in Figure 1.

These charts have been effective for measurements from numerous processes in diverse industries. A further assumption is that the measurement vectors from different sample times are independent. If violated, this leads to the case of autocorrelated data, and suitably modified charts may be needed (see **Autocorrelated Data; Large Autoregressive Integrated Moving Average (ARIMA) Modeling**).

Signal Interpretation

One might presume that a signal from a control chart for a single variable is easier to analyze than MSPC chart. However, it is the process, not a variable, that must be interrogated as part of an OCAP. For example, if the length of an injection-molded part exceeds its control limit, there is not a single dial for part length. Instead, there is a combination of settings for temperatures, pressures, holding times, and so on that might need to be adjusted. The same is true for a multivariate control chart signal – interpretation of the signal and corrective action is not any different. Furthermore, in the previous pump example, a signal is not “caused” by either rpm or pressure differential. It might be caused by a broken blade, or a clog in a pipe. Consequently, the cause is in the process, not from a variable.

Still, in a multivariate control chart, one might eliminate some variables and focus on others that contribute to the signal. This can help corrective actions. If rpm and pressure differential were only two of several variable monitored by MSPC, then the change in the relationship between these two would no doubt benefit diagnosis and OCAP. Methods for identifying contributors to an MSPC signal have received substantial attention (see **Multivariate Control Charts, Interpretation of**).

Conclusions

With modern measurement automation, the importance of MSPC increases. It is now unusual to be concerned with a single measurement. And the ubiquitous computational resources have eliminated the traditional burden of onerous calculations. MSPC is an important tool for modern processes and a rich area for further innovations. Other chapters provide details on many of the topics mentioned here.

GEORGE C. RUNGER

Hotelling's T^2 Chart

Introduction

Statistical process control (monitoring) has a purpose of quickly detecting instances when a process is *out of control* (OC), as indicated by a shift in the statistical distribution of one (univariate) or multiple (multivariate) measures of quality. The Hotelling's T^2 **control chart** is a tool for simultaneously monitoring the mean of several quality characteristics with a single control chart. This method is particularly well suited for monitoring several correlated quality characteristics (see **Multivariate Control Charts Overview**).

One classification of the various applications depends on the knowledge of the *in-control* (IC) parameters, with *phase II* denoting use of known parameters and two categories of *phase I* denoting imperfectly known parameters [1]. *Stage I* of phase I is a retrospective analysis of historical observations with the simultaneous objectives of estimating the IC distribution and detecting observations likely to have been from a different statistical distribution. *Stage II* of phase I is a prospective, or real time, detection of OC conditions as new observations are obtained, based on the distribution estimated in stage I. Logically the parameter estimates from stage I would be updated at some point after accumulating additional IC history in stage II, but when to do this and what its statistical effects are have not been published. Some authors use the terminology “phase I” (or phase 1) for the retrospective analysis and “phase II” (or phase 2) for the prospective, real-time monitoring with estimated parameters, including the case of perfect estimation of phase II. There are alternatives to the dichotomy of retrospective and prospective analysis in the form of *self-starting* control charts that can begin the real-time monitoring process with very few observations, then simultaneously signal the detection of sustained shifts and smoothly update the parameter estimates [2]. With the *change-point* (see **Change-Point Methods**) paradigm, the entire history of observations (or a large number of the most recent ones to limit computational requirements) is evaluated with each new observation to detect a boundary separating the history into two groups with statistically significantly different mean vectors. An OC signal is given when the test statistic exceeds a

control limit, which may vary with the number of observations [3, 4].

Observations are classified into *rational subgroups* of n observations when the n observations are acquired at nearly the same instant of time so that it is likely that they all have the same statistical distribution. The term *individual observations* applies when the subgroup size is $n = 1$, a situation for which the task of accurately estimating the IC **covariance** matrix in stage I is greatly complicated. With individual observations, the subgroup mean is the single observation.

Hotelling's T^2 Statistic and its Distribution

A basic measure of the statistical (Mahalanobis) distance between two multivariate vectors $\mathbf{x}_1$ and $\mathbf{x}_2$ is $\sqrt{(\mathbf{x}_1 - \mathbf{x}_2)^T \mathbf{\Sigma}^{-1} (\mathbf{x}_1 - \mathbf{x}_2)}$, where the matrix $\mathbf{\Sigma}$ is positive definite, ensuring that the radicand is never negative and is zero only when the two vectors are the same. As the name indicates, the Hotelling's T^2 chart statistic is the square of such a distance, based on the mean vector of a subgroup and the IC mean vector. When specialized to univariate observations with the variance estimated, Hotelling's T^2 is the square of a Student's t statistic. Hotelling's T^2 chart is called a *multivariate Shewhart chart*. Although a univariate Shewhart chart has upper and lower control limits, they are symmetrical about the process mean, so that a control chart signal can be uniquely related to the distance of a subgroup mean from the IC process mean, as with Hotelling's T^2 chart. Professor Harold Hotelling introduced the multivariate generalization and gave its distribution [5], also noting its invariance to any linear transformation of the measurements $\mathbf{y} = \mathbf{A}\mathbf{x} + \mathbf{b}$, where $\mathbf{A}$ is a nonsingular matrix. A common early reference for Professor Hotelling's work is an article that appeared later and gave a specialized bivariate application [6], but that work lacks a matrix formulation and generalization beyond two dimensions.

The classic form for Hotelling's T^2 statistic [5] applies in stage II, with the formula $T_s^2 = n(\bar{\mathbf{x}}_s - \bar{\bar{\mathbf{x}}})^T \bar{\mathbf{S}}^{-1} (\bar{\mathbf{x}}_s - \bar{\bar{\mathbf{x}}})$, which is also given in [7, p. 216] and [8, p. 366], where $\bar{\mathbf{x}}_i = n^{-1} \sum_{j=1}^n \mathbf{x}_{i,j}$ is the mean vector of subgroup i and $\bar{\bar{\mathbf{x}}}$ denotes the mean vector of a subgroup “subsequent” to (and not included in) the estimation sample of m subgroups. The grand mean vector is $\bar{\bar{\mathbf{x}}} = m^{-1} \sum_{i=1}^m \bar{\mathbf{x}}_i$, and

$\bar{\mathbf{S}} = m^{-1} \sum_{i=1}^m \bar{\mathbf{S}}_i$ is the mean of the subgroup covariance matrices, $\bar{\mathbf{S}}_i = (n-1)^{-1} \sum_{j=1}^n (\mathbf{x}_{i,j} - \bar{\mathbf{x}}_i)(\mathbf{x}_{i,j} - \bar{\mathbf{x}}_i)^T$. Wierda [9, p. 151] gives the distribution of T_s^2 as $(p(m+1)(n-1)/m(n-1) - p + 1)F_{p, m(n-1)-p+1; \tau^2}$, where p is the number of elements (quality measurements) in each measurement vector $\mathbf{x}_{i,j}$, and $\tau^2 = (mn/m+1)(\boldsymbol{\mu}_s - \boldsymbol{\mu}_0)^T \boldsymbol{\Sigma}^{-1}(\boldsymbol{\mu}_s - \boldsymbol{\mu}_0)$ is the noncentrality parameter based on the true mean vector of the subsequent subgroup $\boldsymbol{\mu}_s$, the true IC mean vector $\boldsymbol{\mu}_0$, and the true covariance matrix for single observations $\boldsymbol{\Sigma}$. The OC properties depend on a shift in the mean vector only through the noncentrality parameter, so that shifts having the same value of the noncentrality parameter result in T^2 statistics having the same statistical distributions.

The *average run length* (ARL) (see **Average Run Lengths and Operating Characteristic Curves**) is the average number of observations until a signal, with performance typically specified by an IC ARL₀ and an OC ARL₁ that is based on some specific shift in the mean vector. The *upper control limit* (UCL) for a specified ARL₀ is $(p(m+1)(n-1)/m(n-1) - p + 1)F_{\alpha; p, m(n-1)-p+1; 0}$, where $\alpha = 1/\text{ARL}_0$ and $F_{\alpha; p, m(n-1)-p+1; 0}$ is the $(1-\alpha)$ quantile (which is the **100(1- α) percentile**) of the (central) F distribution with numerator **degrees of freedom** p and denominator degrees of freedom $m(n-1) - p + 1$.

Numerical Example

As an example of the calculations, suppose that each subgroup has $n = 5$ observations consisting of measurement vectors of $p = 2$ elements and ARL₀ is 370.4, so that α is 0.0027. With an IC estimation sample of $m = 50$ observations, the UCL is $(2(50+1)(5-1)/50(5-1) - 2 + 1)F_{0.0027; 2, 50(5-1)-2+1; 0} = (392/199)6.094 = 12$. Suppose the estimated parameters are means of 55.5 and 33.3, variances of 4.68 and 2.76, and a covariance of 2.52. With a new subgroup mean vector of 53.45 and 33.6, the deviations from the overall means are -2.05 and 0.3. The inverse of the covariance matrix is $\begin{bmatrix} 0.420 & -0.384 \\ -0.384 & 0.713 \end{bmatrix}$. The first product of the quadratic form is $[-2.05 \quad 0.30] \begin{bmatrix} 0.420 & -0.384 \\ -0.384 & 0.713 \end{bmatrix} = [-0.977 \quad 1.001]$, so that the T^2 statistic for this subgroup is $5[-0.977 \quad 1.001] \begin{bmatrix} -2.05 \\ 0.30 \end{bmatrix} = 11.51$.

Since this statistic is less than the UCL, no signal is given for this subgroup. If the OC distribution had a shift in the mean vector of, say $[1 \quad 0.5]$, and the true covariance matrix was the same as the estimate from the sample, then the noncentrality parameter would be $\tau^2 = (50(5)/50+1)[1 \quad 0.5] \begin{bmatrix} 0.420 & -0.384 \\ -0.384 & 0.713 \end{bmatrix} \begin{bmatrix} 1 \\ 0.5 \end{bmatrix} = 4.902[0.228 \quad -0.027] \begin{bmatrix} 1 \\ 0.5 \end{bmatrix} = 1.053$. The probability a chart statistic would exceed the UCL is the same as that of a random draw from the F distribution exceeding $(m(n-1) - p + 1/p(m+1)(n-1))\text{UCL} = (50(5-1) - 2 + 1/2(50+1)(5-1))12 = 6.094$, which is 0.01522, so the OC ARL₁ would be 65.7. Additional examples are given in [10–12].

General Form and Form for Phase II

The general case of the T^2 distribution is given by [13, p. 74] as the distribution of the statistic $Q = \mathbf{y}^T(\mathbf{W}/f)^{-1}\mathbf{y} \sim T_{p,f}^2$, where $\mathbf{y}$ has a multivariate **normal distribution** with zero mean vector, $\mathbf{W}$ is independently distributed as a Wishart with f degrees of freedom, and a common covariance matrix is shared by $\mathbf{y}$ and $\mathbf{W}$, of which $\mathbf{W}/f$ is an unbiased estimator. Equivalently, $(f - p + 1/fp)Q \sim F_{p, f-p+1; 0}$. Since $\bar{\mathbf{x}}_s$ requires division of a sum of random vectors by n and $\bar{\bar{\mathbf{x}}}$ requires division of an independent sum by mn , the expression $(\bar{\mathbf{x}}_s - \bar{\bar{\mathbf{x}}})\sqrt{mn/(m+1)}$ has zero mean and the same covariance matrix as a single observation. This gives the general form $T_s^2 = n(\bar{\mathbf{x}}_s - \bar{\bar{\mathbf{x}}})^T(\mathbf{W}/f)^{-1}(\bar{\mathbf{x}}_s - \bar{\bar{\mathbf{x}}}) \sim (m+1/m)(fp/f - p + 1)F_{p, f-p+1}$.

Instead of using $\bar{\mathbf{S}}$, which has $m \times (n-1)$ degrees of freedom, the overall sample covariance matrix $\mathbf{S} = (1/mn - 1) \sum_{i=1}^m \sum_{j=1}^n (\mathbf{x}_{i,j} - \bar{\bar{\mathbf{x}}})(\mathbf{x}_{i,j} - \bar{\bar{\mathbf{x}}})^T$, which ignores the subgrouping and has degrees of freedom $mn - 1$, can be used. With this variation the chart statistic is $T_{s,p}^2 = n(\bar{\mathbf{x}}_s - \bar{\bar{\mathbf{x}}})^T \mathbf{S}^{-1}(\bar{\mathbf{x}}_s - \bar{\bar{\mathbf{x}}})$, with UCL given by $(m+1/m)((mn-1)p/(mn-p))F_{\alpha; p, mn-p; 0}$ in [9, p. 151].

In phase II, when the true parameters are known, Hotelling's T^2 chart is called a χ^2 chart with chart statistic given by $\chi_s^2 = n(\bar{\mathbf{x}}_s - \boldsymbol{\mu}_0)^T \boldsymbol{\Sigma}^{-1}(\bar{\mathbf{x}}_s - \boldsymbol{\mu}_0)$ and UCL = $\chi_{\alpha; p}^2$. As the size of the estimation sample increases, the stage II UCL smoothly decreases and approaches the UCL for phase II. For example, with $n = 5$, $p = 2$, and $\alpha = 0.0027$, the UCL is 12.49 with

$m = 50$ observations, decreasing to 11.89 with 500 observations and decreasing to the χ^2 UCL of 11.83 with “known” parameters.

Statistical Formula for Stage I

In a stage I chart, a subgroup mean $\bar{\mathbf{x}}_i$ from the estimation sample is used to calculate the chart statistic $T_i^2 = n(\bar{\mathbf{x}}_i - \bar{\mathbf{x}})^T \bar{\mathbf{S}}^{-1}(\bar{\mathbf{x}}_i - \bar{\mathbf{x}})$, with UCL given by $(p(m-1)(n-1)/m(n-1) - p + 1)F_{\alpha; p, m(n-1)-p+1; 0}$. All m observations are analyzed at once, so that the concept of specifying an ARL is not meaningful. Instead, performance is described in terms of signal probabilities. The probability of a signal when all observations are from an IC process is the *false signal probability (fsp)* or false alarm probability or similar terminology. Thus, α is the *fsp* for a single observation, often taken to be 0.0027.

Stage I objectives include estimation of the IC parameters for future monitoring in stage II, and OC observations are typically excluded from the estimation set, reducing m accordingly. Special care and attention is required in identifying *all* the OC observations when there is a sustained shift in the mean vector, as all of the affected subgroups *may not be associated with chart statistics that exceed the UCL*. This is so partially because the IC mean vector is not known and is estimated from the observations being analyzed. Another difficulty is that only distance is presented by the chart statistics, without indication of direction. Consider the case of, say, 25 IC observations followed by a set of 25 OC observations with a common mean vector that is shifted from the IC mean vector. The grand mean vector will be the midpoint between the mean vectors of each set. Thus, the group means would be equally distant from the grand mean and would have the same T^2 distance from it (although these distances would not appear on the control chart). The chart statistics for the 50 subgroups tend to have similar distances as well, so that in the plot of the distances (squared), a visually discernable break between the two sets may be lacking. Useful directional information can be obtained by projecting the subgroup mean vectors onto the line joining the mean vectors of the sets and applying a univariate Shewhart chart to the result. This will make it visually evident that one set clusters in a negative direction while the other clusters in a positive direction,

although equally distant from the grand mean. Simple visual interpretation of a T^2 control chart can easily lead to misinterpretation when there is a sustained shift in the mean vector. Especially when only one or a few statistics exceed the UCL it is easy to classify incorrectly the associated subgroups as **outliers** and remove only those subgroups from the estimation sample, because of the visual similarity to the chart pattern when only outlying observations are present. For more discussion on this point (see [14]; **Multivariate Control Charts, Interpretation of**).

Special Issues with Individual Observations in Stage I

In stage I with individual observations ($n = 1$), a covariance matrix cannot be calculated from the single observation in each subgroup, so $\bar{\mathbf{S}}$ cannot be used. Although there are compelling reasons for not doing so, as will be discussed later, there are recommendations to use the sample covariance matrix $\mathbf{S} = (1/(m-1)) \sum_{i=1}^m (\mathbf{x}_i - \bar{\mathbf{x}})(\mathbf{x}_i - \bar{\mathbf{x}})^T$, which is unbiased *only* in the IC condition when all observations are from a common distribution. Tracy *et al.* [15] show that when the process is IC, $T_{i,1}^2 = (\mathbf{x}_i - \bar{\mathbf{x}})^T \mathbf{S}^{-1}(\mathbf{x}_i - \bar{\mathbf{x}})$ has the distribution $((m-1)^2/m)\beta_{p/2, (m-p-1)/2}$, so the UCL would be $((m-1)^2/m)\beta_{\alpha; p/2, (m-p-1)/2}$.

Since the observations are correlated slightly the overall *fsp* is not exactly $1 - (1 - \alpha)^m$ but is close to that for reasonably large values of m . In stage II with $n = 1$ it is reasonable to use $\mathbf{S}$, and the corresponding chart statistic is $T_{s,1}^2 = (\mathbf{x}_s - \bar{\mathbf{x}})^T \mathbf{S}^{-1}(\mathbf{x}_s - \bar{\mathbf{x}})$ with UCL $= (p(m+1)(m-1)/m(m-p))F_{\alpha; p, m-p; 0}$, as given in [7, p. 225].

With larger subgroup size n , the distribution of a subgroup average vector approximates the multivariate normal distribution, although the covariance estimator may be affected by nonnormality. Other multivariate control charts, such as multivariate **exponentially weighted moving average (MEWMA)** (see **Multivariate Exponentially Weighted Moving Average (MEWMA) Control Chart**) and multivariate cumulative sum (**CUSUM**) (see **Multivariate Cumulative Sum (CUSUM) Chart**), can be designed so as to preserve the control chart performance with respect to nonnormal distributions even with individual observations or small subgroup size [16].

The T^2 statistic takes into account the IC correlations among the elements of the measurement vectors

in contrast to an alternative monitoring technique of using univariate control charts applied to each measurement element individually. Thus, a subgroup may have a large T^2 statistic, indicating its mean vector is unusually distant from the IC mean vector with respect to the IC correlations, although none of the individual means is unusually distant from its IC mean, which is generally considered an advantage. It is mathematically possible to standardize the subgroup mean vectors as $\bar{\mathbf{z}}_s = \Sigma^{-1/2}(\bar{\mathbf{x}}_s - \boldsymbol{\mu}_0)$ so that the T^2 statistic for $\bar{\mathbf{z}}_s$ is the simple sum of squares of its elements and each element can be monitored separately with the same performance characteristics maintained.

When a subgroup leads to a signal, it may be helpful to diagnose which element or combination of elements most contributed to the signal, which can be estimated using a *step-down* method as described in [17, 18] (see **Multivariate Control Charts, Interpretation of**). Alternatively, *principal components* can be used [19], but users may have difficulty interpreting principal components and relating a signal for a principal component with a specific special cause of variation. A criticism of monitoring only a few principal components is that they are determined by the IC variation among the elements of a measurement, which may not be the same subspace as shifts in the mean vector with the presence of special causes.

In stage I with individual observations, the sample covariance matrix $\mathbf{S}$ is not unbiased unless all observations are from the same distribution. With numerous IC and OC observations present, the true covariance matrix may be estimated so badly that the T^2 chart fails to signal, a problem referred to as *masking*. For example [20] shows that when $\mathbf{S}$ is used the signal probability actually *decreases* with an increasing size of a step shift in the mean vector when the shift is near the middle of the observations. A simple estimator that is robust to a small number of shifts in the mean vector is based on the vector difference between successive observations. Sullivan and Woodall [20] gave some properties of the T^2 chart based on this estimator, which is not effective in detecting a large number of outliers, and [21] gives formulas for calculation of the control limits. Other estimators such as the *minimum volume ellipsoid* [22] and an estimator given in [20] are useful in detecting isolated outliers but less effective in detecting multiple sustained shifts in the mean vector. Another proposal for detecting multiple shifts and/or multiple

outliers in the mean vector and/or covariance matrix is given by Sullivan and Woodall [23].

Multivariate Exponentially Weighted Moving Average (MEWMA) Control Chart

Introduction

The multivariate **exponentially weighted moving average (MEWMA) control chart** is a tool for simultaneously monitoring several correlated process variables. Historically, univariate charts have been used to determine if a process is in a state of statistical control (*see Control Charts, Overview; Control Charts for the Mean*). If multiple variables need to be considered, then separate charts have been used for monitoring each individual variable. However, many variables that affect the quality of a process are often correlated. Using separate univariate charts assumes that the variables are independent and ignores the **correlation** among them. Multivariate control charts are designed to incorporate the correlation structure of the variables into the chart when determining the state of statistical control of a process (*see Multivariate Control Charts Overview*). The exponentially weighted moving average (EWMA) statistic computes a weighted average over time in an attempt to detect mean changes more quickly.

MEWMA Statistic

To detect small changes in a process mean vector, a commonly used chart is the MEWMA control chart. In the univariate case, the EWMA chart (*see Exponentially Weighted Moving Average (EWMA) Control Chart*) has been shown to provide quicker detection of small changes in the process mean than the traditional $\bar{x}$ chart (*see Control Charts for the Mean*). Extending this to the multivariate situation was proposed by Lowry *et al.* [1]. Given a set of vectors $X_1, X_2, \dots, X_n$ that follow a multivariate **normal distribution** of dimension p with mean vector μ and variance–**covariance** matrix Σ , the MEWMA statistic can be defined as in equation (1)

$$Z_i = R[X_i - \mu_0] + (I - R)Z_{i-1} \quad (1)$$

for $i = 1, 2, \dots, n$ where R is a diagonal matrix, $R = \text{diag}(r_1, \dots, r_p)$ with $0 < r_i \leq 1$, and Z_0 is usually initialized to the target mean vector, μ_0 . The elements of the matrix R may be chosen to reflect the relative importance of the recorded data. If all variables are equally important, then $r_1 = r_2 = \dots = r_p$. Using this choice for the matrix R yields $Z_i \sim N_p(0, \Sigma_z)$ where the variance–covariance matrix is given in equation (2).

$$\Sigma_{z_i} = \frac{r[1 - (1 - r)^{2i}]}{2 - r} \Sigma \quad (2)$$

Since the variance depends on the weights of the previous time periods it increases over time to its limiting value of $\frac{r}{2-r}\Sigma$. For values of $r \geq 0.5$, this limiting value is achieved rapidly. However, for values of $0 < r < 0.5$, it may take more than 25 time periods to get close to this limiting value. Using the exact variances in the series ensures that the probability of a false alarm is constant for all plotted statistics.

Plotted Statistic

The form of the statistic plotted on the control chart depends on whether Σ is known or not. If Σ is known then a χ^2 statistic may be computed as $Q_i^2 = Z_i' \Sigma_{Z_i}^{-1} Z_i$ with an upper control limit based on the χ_p^2 distribution with a false alarm rate of α . If Σ is not known, one can use the sample variance–covariance matrix (S) as an estimate of Σ (*see Multivariate Analysis*) and compute the Hotelling's T^2 value for each successive element of the series, Z_i . The Hotelling's T^2 value is computed as follows: $T_i^2 = Z_i' S_{Z_i}^{-1} Z_i$, where $S_{Z_i} = \frac{r[1 - (1 - r)^{2i}]}{2 - r} S$. The T^2 value can be plotted on a control chart with the upper control limit defined by $\frac{(n-1)p}{n-p} F_{(\alpha, p, n-p)}^{-1}$ where $F_{(\alpha, p, n-p)}^{-1}$ denotes the upper $100(1 - \alpha)$ th percentile of the F distribution with p and $n - p$ **degrees of freedom**. This is similar to the T^2 control chart (*see Hotelling's T^2 Chart*), but replaces observations at time t with the EWMA value computed for time t . In practice, one would prefer to use the χ^2 statistic if Σ is known, since it will result in a smaller **average run length** (ARL). For situations where there is not a great deal of historical data, the Hotelling's T^2 form should be used.

2 Multivariate EWMA Control Chart

Example

A simulated example is constructed with five variables ($p = 5$) and 35 observations. The simulated data represent measurements for five variables ($X_1 - X_5$). The data set contains 36 observations where the last observation, which is out of control, yields a signal. The first 35 data points were generated from an in-control process and used to estimate the sample variance-covariance matrix. Fixing the target mean to be $\mu'_0 = (5, 5, 5, 5, 5)$ the MEWMA vectors were calculated using $r = 0.2$ for all variables. Table 1 contains the original data ($X_1 - X_5$), the MEWMA values ($Z_1 - Z_5$) and the resulting

T^2 statistic for each vector. These T^2 statistics are also plotted in Figure 1. The control limit is computed as $\frac{(n-1) \times p}{n-p} F_{(0.05, p, n-p)}^{-1} = \frac{34 \times 5}{30} 2.534 = 14.357$. In this example the first 35 observations are inside the control limit, but the 36th observation falls above the upper control limit. For this demonstration the false alarm rate was 0.05, which may yield too many false alarms. It is customary to use false alarm rates of 0.01 or less.

Figure 1 MEWMA control chart is based on the computed T^2 statistics

potential problem, it does not indicate which variable or set of variables are problematic. See **Multivariate Control Charts, Interpretation of** for techniques to determine which variable(s) are problematic in such a signal.

MEWMA charts are useful for detecting small shifts in the overall mean. Typically one uses values such as $0 < r \leq 0.2$ for these situations. In practice, some authors have suggested using two simultaneous MEWMA charts, one with a small value for r and another with $r \geq 0.5$. This latter chart will be able to detect large shifts better. Controlling the overall false alarm rate for these combined charts is somewhat problematic and has not been thoroughly addressed in the literature.

There are some difficulties with the MEWMA chart that also need to be addressed. First, there are some computational issues to deal with. However, all of the calculations in the example above were done using Microsoft Excel. Secondly, there is an “inertia” problem that arises when a process that has been in-control shifts out of control. It may take several time periods before the control chart signals. This problem can be diminished to some extent with the combination chart mentioned above. Calculating the false alarm rate for the MEWMA chart can be challenging. Rigdon [2] and [3] has developed an algorithm for computing false alarm rates. Molnau *et al.* [4] have developed a **Markov chain** based algorithm for calculating the false alarm rates. Linderman and Love [5] and Prabhu and Runger [6] discuss the design of MEWMA control charts.

Despite the computation and interpretation challenges of the MEWMA control chart, it is a good

choice when monitoring the mean vector of several correlated process variables. This chart is especially useful when one is interested in detecting relatively small shifts in the mean vector. Competing techniques include the Hotelling’s T^2 control chart (*see Hotelling’s T^2 Chart*) and the multivariate CUSUM control chart (*see Multivariate Cumulative Sum (CUSUM) Chart*). A general discussion of multivariate control chart may be found in **Multivariate Control Charts Overview**.

MICHAEL D. CONERLY

Multivariate Cumulative Sum (CUSUM) Chart

Introduction

Slight deviations of process variables from their target values are inevitable even when the production process is running normally. Under normal process operating conditions, these deviations in the variables are the interplay of multiple small causes, which are practically unavoidable and generally called the *common causes* or *chance causes of variation*. A process operating under common causes of variation is often considered to be statistically *in control* or *stable*. By statistically analyzing the common variation or the in-control process, process monitoring can be established for early detection of shifts to an out-of-control process. By assigning causes of these shifts, corrective actions can be taken and quality can be improved.

Multivariate control charts simultaneously utilize several related measures of process properties for collectively monitoring the statistical state of a process. The intention is rapid detection of abnormal situations and occurrences of faults, which are assumed to shift the process to an out-of-control state and are referred to as *assignable causes of variation*. Although routine practice of multivariate procedures may require computer computations, over the past decade multivariate control charts have been widely utilized in industry and new multivariate control charting techniques have been developed. This is due, at least in part, to the increased use of computers on the production floor and the amplified ability of computers and sensors to capture data on several process properties simultaneously. Various multivariate control charts (see **Multivariate Control Charts Overview**) exist in the literature. Among these multivariate control charts, the Hotelling's T^2 (see **Hotelling's T^2 Chart**; [1]), the multivariate **exponentially weighted moving average** (MEWMA) (see **Multivariate Exponentially Weighted Moving Average (MEWMA) Control Chart**; [2]), and the multivariate cumulative sum (MCUSUM) are the familiar ones.

In this article, the state of the art for the MCUSUM control charts is reviewed. The univariate cumulative sum (CUSUM) (see **Cumulative Sum (CUSUM) Chart**) procedure is described first since it is the

basis of the multivariate extensions. Next, some multivariate extensions to the univariate CUSUM control chart are explained with their descriptions and basic formulas. References are provided for the other MCUSUM procedures. Advantages and disadvantages of each multivariate procedure are discussed.

The Cumulative Sum Procedure

CUSUM control charts are important tools for the real-time, on-line monitoring of *univariate* (with one variable of interest) processes. These charts are especially effective in detecting small to moderate sized shifts in a process mean.

The classical one-sided CUSUM control chart can be derived from a sequential probability ratio test (SPRT) for the mean of a **normal distribution** or from a likelihood-ratio test for a change point in a normal distributed mean. Page [3] used SPRT to develop a one-sided CUSUM control for detecting shifts in the mean of a normal distributed variable. The null and the alternative hypotheses are

$$H_0 : \mu = \mu_0 \text{ and } H_1 : \mu = \mu_1 \quad (1)$$

respectively. Here, μ represents a process mean whose true value is unknown, μ_0 is the known on-target (in-control process) mean value and μ_1 is a specified off-target (out-of-control process) mean value to be detected quickly.

To generate a procedure for monitoring two-sided mean shifts, i.e., the mean μ increases to some value $\mu_1 > \mu_0$ or decreases to some value $\mu_1 < \mu_0$, Page proposed to simultaneously operate two one-sided CUSUMs. These two one-sided CUSUMs are designed typically with the same shift magnitude value δ for the increasing and decreasing off-target means. That is, $\mu_1 = \mu_0 \pm \delta$ and $\delta = |\mu_1 - \mu_0|$. The monitoring problem is easily accomplished with the recursive calculations that signal if either one-sided CUSUM

$$s_t^+ = \max \left(s_{t-1}^+ + \sigma^{-1} \left(y_t - \mu_0 - \frac{\delta}{2} \right), 0 \right) \text{ or} \\ s_t^- = \max \left(s_{t-1}^- + \sigma^{-1} \left(\mu_0 - y_t - \frac{\delta}{2} \right), 0 \right) \quad (2)$$

exceeds a predetermined decision interval, $h(s_t^+ > h$ or $s_t^- > h)$. Here, t denotes the time or sequence

2 Multivariate Cumulative Sum (CUSUM) Chart

index, y denotes the observation on the variable of interest distributed as normal with mean μ and constant variance σ^2 , and the statistics s_i^+ and s_i^- (generally with, $s_0^+ = s_0^- = 0$) are the one-sided upper and lower CUSUMs, respectively. It can be seen from equation (2) that sums are accumulated as the name implies, but an observation is accumulated only if it differs from the on-target mean value by more than one-half the specified shift magnitude δ . Such accumulation of information across successive observations is what makes the CUSUM procedure powerful in detecting small to medium sized shifts in the mean. In fact, this chart is the optimal diagnostic for a shift of the mean from the on-target mean value μ_0 to the off-target mean value μ_1 . Since the development of CUSUM by Page, a large number of studies have evaluated their theoretical and practical properties. A good recent review can be found in Hawkins and Olwell [4].

Multivariate Cumulative Sum Procedures

Several authors have proposed multivariate (multiple variables of interest) extensions to the univariate CUSUM procedure for monitoring processes with multiple related variables. Many of the key steps in the development of these MCUSUM procedures also appear in the construction of the CUSUM control charts for two-sided shifts (Runger and Testik [5]).

There are mainly two general approaches for the multivariate process monitoring problems. One approach comes from the univariate perspective where multiple univariate control charts are used simultaneously as a collection. Each of the univariate charts in the collection aims in some direction and these charts may be based on measured variables, principal component variables, regression adjusted variables, etc. A detailed discussion is provided in Runger and Montgomery [6]. An out-of-control alarm can be triggered individually by any of the univariate control charts of the collection. This approach may be ineffective in detecting some types of assignable causes since the multivariate characteristic of the data is no longer present directly. The other approach comes from the multivariate perspective, which utilizes the relationships between the variables. Multivariate observation vectors or a statistic of multivariate observation vectors are reduced to a scalar statistic by utilizing the relationships among the variables or

the process knowledge before being plotted on a single control chart. Then this single control chart is used for monitoring the variables of the process jointly. In the literature, MCUSUM procedures have been developed using one of these two approaches. However, before going into detail there is one more important characteristic of multivariate control charts that should be explained. Multivariate control charts are one of two types; directionally invariant and direction specific.

Direction-Specific versus Directionally Invariant Control Charts

Let us consider a univariate monitoring problem first. Univariate control charts for monitoring a process mean are specifically designed for the purpose of detecting shifts in the mean along its axis. Since the mean is a scalar value, it does not have a direction but has magnitude. If an **assignable cause** results in a shift of the mean, the shifted mean value relative to the on-target mean value would be either an increase or a decrease with some magnitude on the monitored variable's axis. Therefore, a two-sided control chart is used when both increases and decreases in the mean are important to detect. Consider the two-sided CUSUM chart in equation (2) where the δ term used in the upper CUSUM s_i^+ and the lower CUSUM s_i^- is the same. Because the observations are assumed to be distributed as normal, which is symmetric, performance of the two-sided CUSUM chart would be the same, on average, for detecting a mean shift having some magnitude λ , either an increase to $\mu = \mu_0 + \lambda$ or a decrease to $\mu = \mu_0 - \lambda$. Generally, the metric used for performance evaluation of control charts is the **average run length** (ARL), which is the average number of points plotted on a control chart before the control chart signals an alarm the first time. Consequently, ARL performance of the two-sided CUSUM chart is invariant to an increase or decrease of the process mean relative to the on-target mean but depends on the magnitude or equivalently the distance $\lambda(\mu) = |\mu - \mu_0|$ of the shifted mean from the on-target mean.

Now consider multivariate monitoring problems. Suppose that the variables are arranged in a vector. Unlike the scalar process mean values in a univariate setting, multivariate process mean vectors have both magnitude and direction. Due to correlations among the monitored variables, an assignable cause would

often result in a shift of the mean vector with some or all of the on-target mean values being changed. The shifted mean vector may have infinite number of possible shift directions that need to be monitored jointly, if not restricted. One approach to multivariate process mean monitoring is to sensitize the control chart to some known or anticipated shift directions when such process knowledge is available. Therefore, the control chart is expected to perform well in detecting mean shifts in these directions but not necessarily be as effective in other directions. The other approach is to design the control chart to simultaneously look at all shift directions such that the ARL performance is the same, on average, in detecting all mean vectors μ which are equidistant from μ_0 . The distance metric used here as a measure of shift magnitude is the statistical (Mahalanobis) distance, which is the square root of the noncentrality parameter

$$\lambda^2(\mu) = (\mu - \mu_0)' \Sigma^{-1} (\mu - \mu_0) \quad (3)$$

Consequently, a multivariate control chart is called *directionally invariant* if its ARL performance in detecting a shift of the mean from the on-target mean is determined solely by the statistical distance of the shifted mean from the on-target mean. Note that the univariate symmetric two-sided CUSUM in equation (2) is also directionally invariant. On the other hand, a multivariate control chart is *direction specific* if its ARL performance in detecting a shift of the mean from the on-target mean is a function of both the statistical distance and the particular direction of the shifted mean relative to the on-target mean. Multiple univariate control charts aim in specified directions and hence are direction specific.

When selecting a multivariate control chart it is important to consider the types of assignable causes that may affect the process. MCUSUM procedures in the literature are either directionally invariant or direction specific. In the following, considered MCUSUM procedures are classified based on their directional characteristic. Advantages and disadvantages of each are discussed.

The Process Model

Suppose that we have observations on p variables $y_1, y_2, \dots, y_p$ and these are arranged in a $p \times 1$

vector $\mathbf{y}$. Assume a sequence $\mathbf{y}_1, \mathbf{y}_2, \dots$ of the p -dimensional observation vectors and let these successive observation vectors be independent and identically distributed as p -variate normal with known on-target mean vector μ and known and constant $p \times p$ **covariance** matrix Σ , i.e., $\mathbf{y}_t \sim N_p(\mu, \Sigma)$ at time t . In the following, the vector μ will represent a multivariate normal process mean whose true value is unknown. Several cases when testing a shift in the mean vector from a known on-target value μ_0 will be considered by using the characteristics of the off-target mean vector.

Direction-Specific MCUSUM Procedures

Let us first consider the simplest case where the off-target mean vector is known in terms of both magnitude and direction. Denote this anticipated off-target mean vector by μ_1 . Note that the on-target and off-target process distributions are completely specified as $\mathbf{y}_t \sim N_p(\mu_0, \Sigma)$ and $\mathbf{y}_t \sim N_p(\mu_1, \Sigma)$, respectively. The null and alternative hypotheses are

$$H_0 : \mu = \mu_0 \text{ and } H_1 : \mu = \mu_1 \quad (4)$$

respectively. To detect a mean shift in one particular direction, a univariate CUSUM chart aimed in that one direction will give the best ARL performance. The solution introduced by Healy [7] is to apply a univariate CUSUM based on a linear combination of the observed variables. For two-sided shifts along the direction of the off-target mean vector, the chart signals if either

$$\begin{aligned} s_t^+ &= \max \left(s_{t-1}^+ + \mathbf{a}'(\mathbf{y}_t - \mu_0) - \frac{\delta}{2}, 0 \right) > h \text{ or} \\ s_t^- &= \max \left(s_{t-1}^- + \mathbf{a}'(\mu_0 - \mathbf{y}_t) - \frac{\delta}{2}, 0 \right) > h \end{aligned} \quad (5)$$

Here, δ is equal to the Mahalanobis distance of μ_1 to μ_0 , i.e., $\lambda(\mu_1)$ and the vector of the linear combination coefficients is $\mathbf{a} = \Sigma^{-1}(\mu_1 - \mu_0)/\delta$. The terms $\mathbf{a}'(\mathbf{y}_t - \mu_0)$ and $\mathbf{a}'(\mu_0 - \mathbf{y}_t)$ both have a standard univariate normal distribution when $\mu = \mu_0$. All of the available theory for designing univariate CUSUM charts and ARL performance analysis can be used for this MCUSUM chart.

Nevertheless, the solution is not very general since the shifted mean needs to be known exactly in terms of magnitude and direction. If the mean shifts some

4 Multivariate Cumulative Sum (CUSUM) Chart

other direction, this procedure may be anything from fairly effective to ineffective.

The problem is more interesting when it is only assumed that the process mean vector $\boldsymbol{\mu}$ has a known shift magnitude δ (in terms of the Mahalanobis distance of $\boldsymbol{\mu}$ to $\boldsymbol{\mu}_0$) but unknown direction when the process experiences a mean shift. Consider the following null and alternative hypothesis, respectively

$$H_0 : \boldsymbol{\mu} = \boldsymbol{\mu}_0 \text{ and } H_1 : \{\boldsymbol{\mu} | \lambda(\boldsymbol{\mu}) = \delta\} \quad (6)$$

It is convenient to standardize the observation vectors as

$$\mathbf{z}_t = \boldsymbol{\Sigma}^{-1/2}(\mathbf{y}_t - \boldsymbol{\mu}_0) \quad (7)$$

where $\boldsymbol{\Sigma}^{-1/2}$ is a square root of $\boldsymbol{\Sigma}$. In terms of $\mathbf{z}$, we can write

$$H_0 : \boldsymbol{\mu} = \mathbf{0} \text{ and } H_1 : \{\boldsymbol{\mu} | \|\boldsymbol{\mu}\| = \delta > 0\} \quad (8)$$

where $\|\cdot\|$ denotes the norm of a vector. One obvious solution to this problem is to apply a set of p two-sided CUSUM charts, one for each element of the vector $\mathbf{y}$ or one for each element of the vector $\mathbf{z}$. Woodall and Ncube [8] essentially considered this approach.

Charts based on $\mathbf{y}$ have the drawback that they do not directly use the **correlation** between the variables. Charts based on $\mathbf{z}$ have the advantages accrued from a principal components transformation and this is a rather natural choice. This is well known to be easily accomplished with the recursive calculations that signal if either

$$\begin{aligned} s_t^+(j) &= \max \left[s_{t-1}^+(j) + \mathbf{z}_t(j) - \frac{\delta(j)}{2}, 0 \right] > h \text{ or} \\ s_t^-(j) &= \max \left[s_{t-1}^-(j) - \mathbf{z}_t(j) - \frac{\delta(j)}{2}, 0 \right] > h \end{aligned} \quad (9)$$

Here, the index $j(j = 1, 2, \dots, p)$ is used to indicate the parameters of the CUSUM chart for the j th component $\mathbf{z}(j)$ of the standardized observation vector $\mathbf{z}$. Runger and Testik [5] proposed to name this MCUSUM procedure as MPYRAMID due to its geometric characteristic. Because the collection of CUSUM charts is considered as a single monitoring procedure, it is necessary to adjust the decision interval h of the charts to keep the total false alarm probability low. A method for selecting h and determining the total false alarm probability is given in Woodall and Ncube [8].

The ARL performance of the MPYRAMID chart depends on the direction of the shift vector and this dependency is lessened, but not removed, by the use of principal component variables $\mathbf{z}(j)$ rather than original variables. It is important to consider the type of mean shift that is important to detect. Charts based on $\mathbf{y}$ would aim along the axes of the original variables and would generally do a good job in detecting shifts along these axes. However, they may not be as effective in detecting shifts in a different direction such as a principal components axis. On the other hand, the MPYRAMID chart based on $\mathbf{z}$ would aim along the axes of the principal component variables and would generally do a good job in detecting shifts along these axes. Similarly, these charts may not be as effective in detecting shifts in different directions such as the axes of original variables.

Directionally Invariant MCUSUM Procedures

For a known off-target magnitude δ but unknown direction another approach is to apply a generalized likelihood-ratio (GLR) procedure. This procedure signals if

$$g_t = \max_{1 \leq \tau \leq t} \left[\delta \left\| \sum_{i=\tau}^t \mathbf{z}_i \right\| - \frac{\delta^2}{2}(t - \tau + 1) \right] > c \quad (10)$$

Here, g is the control statistic, τ is an unknown shift time ($1 \leq \tau \leq t$), and c is a decision interval. The derivation was provided by Basseville and Nikiforov [9]. This MCUSUM procedure is referred to as *MCONE* by Runger and Testik [5] because of its geometric characteristic.

Unfortunately, simplification of the procedure by recursive calculations is not available. However, an advantage of *MCONE* is that it is equally sensitive to shifts of the same magnitude (Mahalanobis distance) in all directions from the on-target mean. Consequently, it can be thought of as a collection of two-sided CUSUM charts operated in all directions simultaneously.

An example *MCONE* chart is shown in Figure 1 for a multivariate normal process monitoring problem with seven variables. Here the mean shifts to an off-target value at time 15 and the chart triggers an alarm at time 18. To illustrate how the calculations are performed, the control statistic g plotted on the control chart is calculated for the

Figure 1 An example of the MCONE control chart

Table 1 An example of the MCONE calculations ($\delta = 1$)

t	τ	$\left\ \sum_{i=\tau}^t \mathbf{z}_i \right\ - \frac{1}{2}(t - \tau + 1)$	g_t
1	1	$3.83 - 0.5 = 3.33$	3.33
2	2	$2.37 - 0.5 = 1.87$	$\max(1.87, 4.40) = 4.40$
2	1	$5.40 - 1.0 = 4.40$	
3	3	$2.96 - 0.5 = 2.46$	$\max(2.46, 3.46, 6.09) = 6.09$
3	2	$4.46 - 1.0 = 3.46$	
3	1	$7.59 - 1.5 = 6.09$	

first three observation vectors as given in Table 1. Note that the value for δ is selected to be 1 in the calculations and the first three observation vectors are

$$\begin{aligned} \mathbf{z}_1 &= [-2.28 \quad 0.06 \quad 1.86 \quad -1.45 \quad 1.46 \\ &\quad -0.52 \quad 1.23]' \\ \mathbf{z}_2 &= [0.04 \quad -1.42 \quad 0.63 \quad -1.03 \quad 1.44 \\ &\quad -0.19 \quad -0.22]' \\ \mathbf{z}_3 &= [-2.26 \quad 0.08 \quad 0.03 \quad -0.56 \quad 1.43 \\ &\quad -0.45 \quad -1.04]' \end{aligned}$$

Other MCUSUM Procedures

Another direction-specific procedure for multivariate observations is the CUSUM of regression adjusted variables proposed by Hawkins [10]. Hawkins extended the approach of a known shift direction to the case in which several shift directions of interest are specified. Some other directionally invariant MCUSUM procedures in the literature include the COT and MCUSUM of Crosier [11] and MC1 and MC2 of Pignatiello and Runger [12]. Of these procedures, MCUSUM and MC1 are the ones with better performance. Although these two MCUSUM procedures have no known optimality properties, they have good practical performance. However, for these two procedures worst-case scenarios exist such that their steady-state performance is impacted by an accumulation of data in one direction before the process shifts another direction, namely the inertia problem. This is because one distinctive characteristic of univariate CUSUM procedure, that is that the steady-state performance is superior to the initial performance, does not appear in these charts. A detailed discussion of the MCUSUM procedures considered in this article as well as some others with performance comparisons can be found in Runger and Testik [5].

Summary

There are several multivariate extensions to the univariate CUSUM control chart. This work reviewed some of these multivariate extensions and compared their advantages and disadvantages. Basic formulas were provided and references were given to allow the interested reader to investigate further.

Multivariate Charts for Variability

Introduction

Multivariate control charts (*see Multivariate Control Charts Overview*) which are specifically designed to detect changes in a **covariance** matrix are discussed here. The covariance matrix represents the variability of a multivariate process. The scope of the discussion is limited to phase II **control charts** for multivariate normal processes. For a more detailed account of the topic being discussed, readers are referred to the works by Weirda [1], Lowry and Montgomery [2], Montgomery [3], and Yeh *et al.* [4], and the references therein (*see Hotelling's T^2 Chart; Multivariate Exponentially Weighted Moving Average (MEWMA) Control Chart; Multivariate Cumulative Sum (CUSUM) Chart*).

Let $X = (X_1, X_2, \dots, X_p)'$ denote the random variable that represents the p correlated quality characteristics derived from a process whose quality is to be monitored. When the process is in control, it is assumed that X follows a p -dimensional **normal distribution**, denoted by $N_p(\mu_0, \Sigma_0)$, where μ_0 is the in-control process mean and Σ_0 is the in-control process covariance matrix. On the other hand, when the process is out of control, it is assumed that X follows $N_p(\mu, \Sigma)$, where either $\mu \neq \mu_0$ or $\Sigma \neq \Sigma_0$ or both. The in-control parameters μ_0 and Σ_0 are assumed to be either known or that they can be sufficiently estimated at the end of phase I control such that their values can be assumed known prior to the beginning of the phase II monitoring. Here we discuss two phase II multivariate control charting techniques for detecting changes in the covariance matrix, each dependent on how the samples of observations are collected. In the first case, independent samples of $n(n > p)$ observations each are repeatedly drawn. In the second case, independent individual observations ($n = 1$) are being drawn from the process.

The $|S|$ Chart

In the case when independent samples each with n observations are available for constructing the control chart, a commonly used Shewhart control

chart is known as the $|S|$ chart (*see Multivariate Control Charts Overview*), or the generalized variance chart. For the t th sample, $t = 1, 2, \dots$, the n observations are denoted by $X_{t1}, X_{t2}, \dots, X_{tn}$, and the corresponding sample mean and covariance matrix are $\bar{X}_t = \sum_{j=1}^n X_{tj}/n$ and $S_t = \sum_{j=1}^n (X_{tj} - \bar{X}_t)(X_{tj} - \bar{X}_t)'/(n-1)$, respectively. To construct the $|S|$ chart, one calculates $|S_t|$, $t = 1, 2, \dots$, the determinant of the sample covariance matrix of the t th sample and plots $|S_t|$ against the sampling sequence t . For 3σ control limits, the upper control limit (UCL), center line (CL), and lower control limit (LCL) of the $|S|$ chart are defined as

$$UCL = \left(1 + 3\frac{\sqrt{b_2}}{b_1}\right) |\Sigma_0| \quad (1)$$

$$CL = |\Sigma_0| \quad (2)$$

$$LCL = \max\left(0, \left(1 - 3\frac{\sqrt{b_2}}{b_1}\right) |\Sigma_0|\right) \quad (3)$$

where $b_1 = (n-1)^{-p} \prod_{i=1}^p (n-i)$ and $b_2 = (n-1)^{-2p} \left[\prod_{i=1}^p (n-i)\right] \times \left[\prod_{j=1}^p (n-j+2) - \prod_{j=1}^p (n-j)\right]$. An out-of-control signal is detected if $|S_t|$ plots outside of the control limits.

We next present the application of the $|S|$ chart using a real-life example. The example from Mitra [5] is related to a component used in the assembly of a transmission mechanism. Two correlated quality characteristics, tensile strength and diameter, are to be monitored. The data set consists of 20 independent samples each with four observations. In this case, $p = 2$ and $n = 4$, which result in $b_1 = \frac{2}{3}$ and $b_2 = \frac{84}{81}$. The centerline $|\Sigma_0|$ was estimated by the average of the sample covariance matrices of all 20 samples which turned out to be 48.4. Therefore the UCL , CL , and LCL were calculated to be 270.1, 48.4, and 0, respectively. The $|S|$ chart, which was produced using Minitab, is shown in Figure 1. The $|S|$ chart indicated that the covariance matrix was in control.

The MEWMS Chart

In the case when only independent individual observations are available, the $|S|$ chart is no longer applicable since the sample covariance matrix does not exist. The alternative is to find other ways to pool observations together and derive control charts based on the pooled observations. Let $Z_t = \Sigma_0^{-1/2}(X_t -$

2 Multivariate Charts for Variability

Figure 1 The $|S|$ chart of the transmission assembly example

μ_0), $t = 1, 2, \dots$, be the transformed variable of the t th observation X_t such that when the process is in control Z_t follows $N_p(0, I_p)$, where I_p is a $p \times p$ identity matrix. Let $V_t = \lambda Z_t Z_t' + (1 - \lambda)V_{t-1}$, where $0 < \lambda < 1$ is a smoothing constant and $V_0 = Z_1 Z_1'$. For each sampling sequence t , one calculates $\text{trace}(V_t)$, the trace of the matrix V_t . The values of $\text{trace}(V_t)$ are then plotted on the control chart against the sampling frequencies. For 3σ control limits, the UCL, CL, and LCL are defined as

$$UCL = p + L \sqrt{2p \sum_{i=1}^t c_i^2} \quad (4)$$

$$CL = p \quad (5)$$

$$LCL = p - L \sqrt{2p \sum_{i=1}^t c_i^2} \quad (6)$$

where L is a multiplier dependent on p, λ and the desired in-control chart performance, and $\sum_{i=1}^t c_i^2 = \lambda(2 - \lambda)^{-1} + 2(2 - \lambda)^{-1}(1 - \lambda)^{2t-1}$ which converges to $\lambda/(2 - \lambda)$ as $t \rightarrow \infty$. Using simulations, Huwang *et al.* [6] provided the values of L for λ ranging from 0.1 to 0.9 and $p = 2$ and 3, such that when the process is in control the control chart will have an in-control **average run length** approximately equal to 370, which is equivalent to a 3σ limits Shewhart chart. Part of the tabulated

values of L is provided in Table 1. Note that the chart, called the *multivariate exponentially weighted moving squared-deviation* (MEWMS) chart, is a multivariate extension of the univariate EWMS control chart first proposed by MacGregor and Harris [7]. In general, a smaller value of λ , say $0.1 \leq \lambda \leq 0.3$, gives a better performance of the MEWMS chart – in term of faster detection of out-of-control processes.

Next we present the application of the MEWMS chart. The data were taken from Joshi and Sprague [8] for an application in the semiconductor industry. The observations were related to the quality of wafer manufacturing during photolithography process. There were 74 lots of wafers and one wafer was randomly taken from each lot. Three correlated critical dimension measurements of die were taken on each drawn wafer. Using these samples, except lot 40 which was classified to be out of control, estimates of μ_0 and Σ_0 were obtained and used to establish the control limits for phase II monitoring. The estimates

Table 1 The values of L of the MEWMS chart for $p = 2$ and 3

λ	$L(p = 2)$	$L(p = 3)$
0.1	2.9013	2.8212
0.2	3.4870	3.3281
0.3	3.8713	3.6621

μ_0 and Σ_0 are equal to $\hat{\mu}_0 = \begin{pmatrix} 3.315 \\ 3.108 \\ 3.118 \end{pmatrix}$ and $\hat{\Sigma}_0 = \begin{pmatrix} 0.0093 & 0.0036 & 0.0052 \\ 0.0036 & 0.0085 & 0.0034 \\ 0.0052 & 0.0034 & 0.0088 \end{pmatrix}$, respectively. In phase II, an additional 200 observations were obtained. For every new observation generated, it was transformed using $Z_t = \hat{\Sigma}_0^{-1/2}(X_t - \hat{\mu}_0)$, $t = 1, 2, \dots, 200$. The matrix $V_t = \lambda Z_t Z_t' + (1 - \lambda)V_{t-1}$ was updated and the value of $\text{trace}(V_t)$ was calculated and plotted against the sampling sequence. The process was in control for the first 49 observations. Starting from observation 50, a mean shift occurred in the process and the observations starting from sample 50 were generated from a process having a new mean vector equal to $(3.231, 3.200, 3.118)$ and the same covariance matrix as $\hat{\Sigma}_0$. Beginning at observation 100, an additional change in the covariance matrix also took place. The new covariance matrix starting from sample 100 is equal to $\Sigma = \begin{pmatrix} 0.0186 & 0.0036 & 0.0052 \\ 0.0036 & 0.0170 & 0.0034 \\ 0.0052 & 0.0034 & 0.0088 \end{pmatrix}$. The corresponding phase II MEWMS chart with $p = 3$, $\lambda = 0.2$, and $L = 3.3281$ was produced using S-plus and shown in Figure 2. The MEWMS chart detected out-of-control signals at as early as observation 54, which was primarily due to a mean shift in the process. The chart also showed an out-of-control signal at observation 100 when the change in the covariance matrix actually occurred.

Figure 2 The MEWMS chart of the wafer manufacturing example

Discussion

The $|S|$ chart is relatively easy to construct and use, and it is available in some of the commonly used commercial software packages such as Minitab. It is also less sensitive to mean shifts in the sense that a shift in the mean is less likely to cause the $|S|$ chart to produce false out-of-control signals. On the other hand, the chart is restricted to the case when $n > p$. Tang and Barnett [9] showed such control limits may lead to considerably larger false alarm rate than the nominal value of 0.0027, especially when n is relatively small. In the same paper, they provided accurate calculations of control limits for the cases when $p = 3$ and 4.

Since the $|S|$ chart is a Shewhart chart, it is generally less effective in detecting small changes in the generalized variance. Yeh *et al.* [4] proposed an exponentially weighted moving averages (EWMA) chart based on the EWMA of $\log |S_t|$. Such an EWMA chart is more effective in detecting small changes in the generalized variance. Other existing multivariate control charts for variability derived from the sample generalized variance can be found in works by Guerrero-Cusumano [10], Tang and Barnett [11], Levinson *et al.* [12], Yeh and Lin [13], and Yeh *et al.* [14].

In the case of $n = 1$, none of the aforementioned charts is applicable since the sample covariance matrix cannot be evaluated. The MEWMS chart discussed above is relatively easy to construct. Although most of the commercial software packages currently do not include the MEWMS chart, it was relatively simple for its customized codes. For other charts that are applicable to the case when $n = 1$, readers are referred to the works by Chan and Zhang [15], Khoo and Quah [16], Yeh *et al.* [17], and Reynolds and Cho [18].

Conclusions

We discuss two multivariate control charts for monitoring variability of multivariate normal processes. The $|S|$ chart is applicable when $n > p$, while the MEWMS chart is specifically designed for individual observations ($n = 1$). Examples of other types of charts include the nonparametric procedures designed to detect changes in a covariance matrix as defined by changes of some function of the matrix (Hawkins [19]), the data depth based nonparametric control

charts for nonnormal processes (Liu [20]), and the principle component analysis and dissimilarity index based control charts for multivariate time-series data (Kano *et al.* [21]).

The $|S|$ chart is essentially designed to detect changes in the determinant of the covariance matrix. When a point is outside of the control limits on the $|S|$ chart, caution should be taken when interpreting such a signal (*see Multivariate Control Charts, Interpretation of*). The out-of-control signal is primarily due to a possible increase or decrease in the determinant of the covariance matrix. It does not necessarily imply that there is an increase or decrease in the process variability. Johnson and Wichern [22] gave three covariance matrices for bivariate data that all have the same determinant and yet have very different correlations.

An important area not discussed here is the diagnostic techniques. This is more complicated than the univariate case, mainly due to the complexity of the covariance matrix. Because so many parameters are contained in the covariance matrix and that changes in one or some of the parameters can trigger an out-of-control signal, it is of eminent importance to be able to further pinpoint which of these parameters are out of control. Some potential diagnostics are discussed in Yeh *et al.* [4], and the references therein. In another recent paper, Apley and Shi [23] proposed a technique based on a fault model which transformed the problem of diagnosing into the problem of estimating the number of faults which contribute to changes in process variability and the linear combinations by which each of the p correlated quality characteristics is affected.

Introduction

Statistical process control procedures are designed to work well in a variety of conditions. The general idea is that a stable process containing only common-cause variation is easiest to control, but when the process variation is mixed with special-cause components, statistical input is needed to help monitor the process and detect the changes. One of the goals of a statistical process control (SPC) procedure is to detect the presence of special causes of variation quickly and reliably, and to locate the source of the variation in terms of the process variables so that corrective action may be taken (see **Control Charts, Overview**). This is achieved by using a charting statistic and interpreting the output when it signals that a process change has occurred.

When only one process variable is used to measure process performance, changes in the mean and/or changes in the variation of the variable can be detected using single-variable control charts. When several variables are used to monitor a process, the interpretation of signals in a multivariate control chart is not so simple. In addition to changes in location and variation, there may also be changes in the relationships between the many variables. This occurs when there is a **covariance** or **correlation** change between two variables or among a group of variables. Any of these changes can indicate a signal on the control chart for the multivariate process. For example, a change in the correlation between temperature and pressure might indicate that the observed pressure is either too high or too low for the given observed value of the temperature, relative to the historical process data.

Multivariate process control (see **Multivariate Control Charts Overview**) can be based on observing an individual observation vector, or on observing a statistic, such as a mean vector or covariance matrix estimate, computed from a sample of observations taken at each time period. In general, process industries such as the chemical industry favor monitoring individual observations, while other industries such as the manufacturing industry often monitor

statistics based on the mean of a sample of observations. We will examine signal interpretation for the case where control is based on an individual multivariate observation vector taken in a monitoring stage (labeled phase II). However, the procedures we present can be adapted for control based on the sample mean as well as for phase I operations where a baseline or historical data set (HDS) is being constructed.

Signal Interpretation

One of the more popular multivariate control procedures is based on Hotelling's T^2 statistic (see **Hotelling's T^2 Chart**). Consider a p -dimensional vector of observations, $x' = (x_1, x_2, \dots, x_p)$, that is made on a process at a specified time period. We assume that, when the process is in control, the $\mathbf{x}$ vectors are independent and follow a multivariate **normal distribution** with an unknown mean vector μ and an unknown covariance matrix Σ . The form and distribution of the T^2 statistic for the observation vector $\mathbf{x}$ used in phase II is given by

$$T^2 = (\mathbf{x} - \bar{\mathbf{x}})' \mathbf{S}^{-1} (\mathbf{x} - \bar{\mathbf{x}}) \\ \sim \left[\frac{p(n+1)(n-1)}{n(n-p)} \right] F_{(p, n-p)} \quad (1)$$

The term $F_{(p, n-p)}$ denotes an F distribution with p and $n-p$ **degrees of freedom**, and the estimates, $\bar{\mathbf{x}}$ and $\mathbf{S}$, are obtained from a phase I operation where the created HDS is of size n .

The popularity of the T^2 statistic is due in part to its ease of calculation and also because of the availability of procedures that can be used to interpret its signals. Two well-known procedures are based on using transformations to decompose a signaling T^2 statistic into the sum of p orthogonal components. These orthogonal components can be related to the contributions of individual process variables or groups of variables to the signal. Thus, we are quickly able to determine if the signaling observation vector agrees with the measures of location or variation/covariation of the in-control multivariate distribution.

The oldest of the decomposition procedures is obtained by transforming the signaling T^2 value into a function of the principal components of the estimated covariance matrix, $\mathbf{S}$, or the corresponding estimated correlation matrix. Using the estimated

2 Multivariate Control Charts, Interpretation of

covariance matrix, we define the i th principal component of $\mathbf{S}$ as the linear combination of the p process variables given by

$$z_i = \mathbf{u}_i'(\mathbf{x} - \bar{\mathbf{x}}) \quad (2)$$

for $i = 1, 2, \dots, p$, where $\mathbf{u}_i$ is the i th eigenvector of $\mathbf{S}$ and λ_i is the corresponding eigenvalue [1]. Using this transformation, the T^2 statistic in equation (1) becomes

$$T^2 = \frac{z_1^2}{\lambda_1} + \frac{z_2^2}{\lambda_2} + \dots + \frac{z_p^2}{\lambda_p} \quad (3)$$

Since the principal component in equation (2) is a linear combination of the p process variables, it can be used to identify the groups of variables contributing to the signal. However, it has an inherent weakness in that it cannot provide a straightforward interpretation in terms of specific process variables.

A more efficient procedure, known as the MYT decomposition, is described below. The MYT decomposition [2] is defined by using the following transformation of the p process variables

$$\mathbf{y} = \mathbf{L}^{-1}(\mathbf{x} - \bar{\mathbf{x}}) \quad (4)$$

where $\mathbf{L}$ is a lower triangular invertible matrix with the property that $\mathbf{S} = \mathbf{L}\mathbf{L}'$. Using this transformation, the T^2 statistic in equation (1) becomes

$$\begin{aligned} T^2 &= y_1^2 + y_2^2 + \dots + y_p^2 \\ &= T_1^2 + T_{2,1}^2 + \dots + T_{p,1,2,\dots,p-1}^2 \end{aligned} \quad (5)$$

The T_1^2 term in equation (5) is labeled an unconditional term and the $T_{j,1,2,\dots,j-1}^2$ terms are labeled conditional terms.

Using equation (4), the general form of the unconditional term contained in any phase II decomposition is given as

$$T_j^2 = \frac{(x_j - \bar{x}_j)^2}{s_j^2} \quad (6)$$

where x_j is the j th component of $\mathbf{x}$, and $\bar{x}_j$ and s_j^2 are its corresponding mean and variance estimates as determined using the HDS. Under the assumption of no signal, the T_j^2 statistic is described by an F distribution given as

$$T_j^2 \sim \left(\frac{n+1}{n} \right) F_{(1,n-1)} \quad (7)$$

We use this term to check if the value of the j th variable is outside of its operational range.

Similarly, the general form of the conditional term in any phase II decomposition is given as

$$T_{j,1,2,\dots,j-1}^2 = \frac{(x_j - \bar{x}_{j,1,2,\dots,j-1})^2}{s_{j,1,2,\dots,j-1}^2} \quad (8)$$

This is the square of the value of the j th variable adjusted by the estimates of the mean and variance of the conditional distribution of x_j adjusted for the variables $x_1, x_2, \dots, x_{j-1}$. The estimates, $\bar{x}_{j,1,2,\dots,j-1}$ and $s_{j,1,2,\dots,j-1}^2$, are obtained from the HDS [3]. With no signal present, the distribution of a conditional term is given as

$$T_{j,1,2,\dots,j-1}^2 \sim \left(\frac{(n+1)(n-1)}{n(n-k-1)} \right) F_{(1,n-k-1)} \quad (9)$$

where $k = j - 1$. We use this term to determine if the actual value of the j th variable is close to the value predicted using the values of the remaining variables.

Since the subscripts $\{1, 2, \dots, p\}$ in the T^2 terms on the right-hand side of equation (5) can be replaced by any permutation of $\{1, 2, \dots, p\}$, the corresponding distributions of the T^2 statistics in equations (7) and (9) remain invariant with respect to the permutation.

Computer algorithms based on equation (5) are readily available for determining which of the p process variables are contributing to the signaling T^2 value [4]. Generally, these systems work by examining all possible decompositions of a signaling T^2 value. A total decomposition includes computing all the possible distinct MYT components: the p unconditional terms, T_j^2 ; all two-way conditional terms $T_{i,j}^2$; all three-way terms, $T_{i,j,k}^2$; etc. There are $2^{(p-1)} \times (p)$ such terms, but several efficient computational shortcuts exist for obtaining the relevant values.

For example, a useful stepwise process involves first using the p unconditional terms described in equation (6) to check the tolerance of each individual variable. Any variable with a significant F value as given by equation (7) is declared to be out of tolerance. This variable would then be considered as part of the signal and removed from further consideration. Next the two-way terms are checked using equation (9). Any signaling $T_{i,j}^2$ component implies that the relationship between x_i and x_j differs from that given in $\mathbf{S}$. If there is a signal, both variables

Figure 1 T^2 chart for monitoring the turbine system

are removed from further consideration and the three-way terms are checked and so on.

Data Example

The MYT decomposition procedure is illustrated in the following data example. More details on how to use it and how to interpret its orthogonal components is given in [5]. A steam turbine system is used to generate electricity for industrial use. Our purpose is to show how signal interpretation can be used in locating the source of a signal in this process. To simplify the problem, we consider only two of numerous variables that are used in controlling the turbine system. These variables include the amount of fuel (F) being used and the amount of megawatts (MW) that is being produced by the turbine. Summary statistics for the HDS for the two variables are contained in Table 1.

A typical T^2 control chart used in monitoring the turbine system is given in Figure 1. All T^2

values below the upper control limit (UCL), obtained using an $\alpha = 0.0027$, indicate that performance is in agreement with the baseline conditions. The T^2 values above the UCL indicate signals.

A scatter plot of the turbine data (fuel vs megawatts) along with the corresponding T^2 control ellipse using the formula in equation (1) is presented in Figure 2. Note that the signaling T^2 points identified in Figure 1 are located outside the control ellipse. The two lines in the plot represent the regression of fuel on megawatts (F/M) and the regression of megawatts on fuel (M/F).

In order to illustrate signal interpretation, we apply the MYT decomposition to the four signaling T^2 values corresponding to observations #13, #16, #17, and #22. A total decomposition giving all components and their values for the signaling T^2 values are presented in Table 2. The subscript 1 refers to the megawatt variable while the subscript 2 refers to the fuel variable.

Table 1 Summary statistics for the historical data set

	MW	F
Mean	53.72	692.45
Standard deviation	3.41	30.41
Correlation matrix		
	MW	F
MW	1.000	0.7469
F	0.7469	1.000

Discussion of Results

Observation #13, located at the lower end of the control ellipse, has a significant unconditional component T_1^2 and a significant conditional component $T_{1,2}^2$. The signaling unconditional term, T_1^2 , indicates that the megawatt value is outside the tolerance limits (i.e., range) established using the HDS. The signaling conditional term, $T_{1,2}^2$, indicates that, given the value of fuel for this observation, the value of megawatts is not where it should be relative to the

Figure 2 Scatter plot of data

HDS. This is further denoted by the large vertical distance (residual) between the observation and the regression line of megawatts on fuel (M/F) given in Figure 2.

Both of the T^2 conditional terms for observations #16 and #17 are significant. These signals indicate that there is a fouled linear relationship between the megawatts being produced and the fuel being used, and that the two variables are countercorrelated relative to the correlations observed using the HDS. From the plot given in Figure 2, it appears that for these two observations either the megawatts value is too low for the given value of fuel, or the fuel value is too high for the given value of megawatts.

Observation #22, located at the upper end of the control region given in Figure 2, has a significant unconditional term T_2^2 . This indicates that the fuel usage for this observation is outside the tolerance limits (i.e., range) established using the HDS.

When only two variables are being considered, making it possible to plot the control ellipse, we usually find that points located outside the ends of the ellipse, such as observation #22 in our example, have out-of-tolerance variables. Those observations

located around the middle, but outside of the control ellipse, such as observations #16 and #17 in our example, will have fouled relationships between the two variables. Similarly, those observations located between the middle and the end, but outside of the ellipse, such as observation #13 in our example, may have both problems.

Summary

The MYT decomposition has many good features. It provides an orthogonal decomposition of a T^2 value, and the corresponding components indicate which variables in the signaling observation vector disagree with the historical data. The cause of the signal can be directly attributed to a variable or set of variables being out of tolerance, and/or to the correlation between a set of variables being counter to the correlation observed in the baseline data. What it does not answer is whether the cause of the problem is due to a change in the mean vector or to a change in the covariance matrix, since either could produce variables that are out of tolerance and/or

Table 2 Decomposition components of T^2 signals

Observation	#13	#16	#17	#22
T_1^2	6.4940 ^(a)	0.2094	0.0967	2.4639
$T_{2,1}^2$	0.2580	8.2104 ^(a)	7.2936 ^(a)	4.0189
T_2^2	2.4515	2.4441	2.4441	6.2770 ^(a)
$T_{1,2}^2$	4.3005 ^(a)	5.9758 ^(a)	4.9462 ^(a)	0.2059

^(a)Indicates significant using $\alpha = 0.0027$

countercorrelated. This problem also exists when one uses principal components analysis. In these types of decompositions, we are basically identifying the change and not necessarily isolating the mechanism leading to the change.

Other approaches exist for use in interpreting T^2 signals. Several of these have been shown to be related to the components of the MYT decomposition (see [2]), though none are as comprehensive. These include the method in [6, 7] based on using regression-adjusted variables to improve diagnostics as well as the step-down method in [8, 9] that sequentially tests subsets of the variables assuming there is an *a priori* ordering of the variables. Another related procedure [10] is based on using a univariate t statistic to rank the components of an observation vector according to their contribution to the signal. And in [11] a method is given that is a function of a sum of a subset of the conditional T^2 components.

Signal interpretation can also be accomplished using other techniques. Fuchs and Benjamin [12] present a graphical method based on multivariate profile plots, while Sparks *et al.* [13] use the Gabriel biplot. Kouti and MacGregor [14] provide an approach based on usage of normalized principal components and contribution plots. Maravelakis *et al.* [15] propose a modified approach based on principal components. Nedumaran and Pignatiello [16] describe an approach based on Scheffe-type intervals and usage of univariate diagnostic charts for the individual variables as well as univariate charts for the principal components. Although the list of alternative methods for interpreting signals in a multivariate control chart continues to expand, orthogonal decomposition techniques, particularly those based on the MYT decomposition or principal components, remain the most useful and informative.

Autocorrelated Data

Introduction

Traditional statistical process control (SPC) assumes that consecutive points plotted on a control chart are independent (*see Control Charts, Overview*). In the case that individual observations (rather than means computed from subgroups) are being plotted, then the typically assumed process can be described by the simple relationship

$$y_t = \mu + a_t \quad (1)$$

where

y_t = the quality variable of interest at time t

μ = the mean of the process

a_t = the random error at time t .

As early as the 1970s, however, researchers recognized that in practice observations are often serially autocorrelated (see [1–3] as examples). Observations that are autocorrelated are not independent and future observations can be predicted from those in the past. When a process is positively autocorrelated, the observations tend to follow each other or have inertia. Patterns that arise from such serial **autocorrelation** look almost sinusoidal in nature because of the similarity of consecutive observations. Observations that are negatively autocorrelated, on the other hand, show an alternating pattern, where subsequent observations move in the opposite direction to that of previous observations. In manufacturing settings, positive autocorrelation is by far the most commonly encountered deviation from independence. As the use of statistical monitoring tools spreads to new applications such as medical surveillance, however, more examples of negatively correlated process are likely to emerge.

Harris and Ross [4] reported that measured variables from tanks, reactors, and recycle streams in chemical processes show significant serial correlation and Wardell *et al.* [5, 6] motivated their work with an example from an extrusion process. Hence autocorrelation manifests itself in both continuous and discrete processes. The problem has been magnified in more recent times with the advent of automatic sensors. Such sensors allow for continuous measurement in

which the sampling frequency approaches infinity. Such a high sampling frequency almost always results in observations that are not independent, but instead autocorrelated (see [7] for example).

Under such conditions traditional SPC procedures may be ineffective, indeed inappropriate for monitoring, controlling, and improving process quality. A common result of applying standard Shewhart control charts (in particular, individuals and moving range charts) to processes exhibiting positively autocorrelated data is an increase in the number of false alarms, i.e., the number of times that a point falls outside of the control limits when in reality the process characteristics have remained stable. False alarms have the potential to be very costly, especially in environments in which operators are empowered to shut down the operation when a signal is generated from the control chart.

Figure 1(a) shows an individuals control chart applied to simulated data that mimic an AR(1) process with an autoregressive parameter equal to 0.65. Such a process is positively autocorrelated. For the first 50 observations, the mean and the process remained constant (i.e., no parameters changed). At point 51, a shift in the mean of two standard deviations (of the error terms) was introduced (indicated by the vertical line). The inside limits are those that were calculated by using the moving range to estimate the standard deviation. The figure shows multiple points that fall outside the inner limits, which are false alarms. The outer limits were formed by using the sample standard deviation of the first 50 points. No points fall outside those limits, including after the point of the shift. Hence there is a reduction in the number of false alarms, but at the expense of not detecting a true process change. Figure 1(b) will be discussed later.

Because of the difficulties of monitoring autocorrelated processes with traditional control charts, researchers and control chart designers sought ways to account for the autocorrelation. The next section introduces the two most commonly used approaches.

Common Approaches to Monitor Autocorrelated Data

Soon after the problem of autocorrelation was uncovered, researchers began to propose solutions that can broadly be divided into two categories. The first

Figure 1 A comparison of a standard Shewhart chart to a residual chart when applied to a positively autocorrelated process. (a) The inner limits of the Shewhart chart are created by using a moving range and produce multiple false alarms. The outer limits are created using an overall standard deviation and do not detect shifts quickly (b) A residual chart typically shows a spike at the point of change and then settles down again after the change

approach was to adjust the control chart limits to compensate for the autocorrelation. In other words, if the problem was an excessive number of false alarms, then the control limits could be widened to reduce the false signals. Vasilopoulos and Stamboulis [3] adjusted Shewhart X-bar chart control chart constants (see **Control Charts for the Mean**) for the case of AR(2) processes. Others followed with similar studies of cumulative sum (CUSUM) (see **Cumulative Sum (CUSUM) Chart**) and exponentially weighted moving average (EWMA) (see **Exponentially Weighted Moving Average (EWMA) Control**

Chart) charts (see [8, 9] for example). The obvious problem with the limit-adjusting approach is that widening the control limits reduces the probability of detecting a true change in the process. Still, the approach is relatively simple to implement and often has better performance than other methods.

The second approach that emerged and gained considerable popularity was to fit the data using an appropriate statistical model and then compute and monitor the **residuals**, or unexplained portion of the model. Although others may have hinted at it earlier,

Alwan and Roberts [10] were the first to formalize the residual-monitoring approach. They introduced the possibility of two “charts”: a common-cause chart that showed the fitted values from the statistical model (but had no control limits); and a special-cause chart that was an individuals control chart of the residuals from the statistical model. If the optimal statistical model was found, the residuals would adhere to the traditional assumptions of SPC and hence a Shewhart control chart would be appropriate.

Alwan and Roberts were quite general in their suggestions of appropriate statistical models that could be used to account for the common-cause variation. They discussed regression models as well as time series, or Box–Jenkins models [11] (*see Time Series Analysis; Large Autoregressive Integrated Moving Average (ARIMA) Modeling*). The time-series approach was the one that was embraced by most subsequent researchers and it was almost forgotten that Alwan and Roberts had proposed a much more general idea.

The time-series approach called for fitting the model with a general autoregressive integrated moving-average (ARIMA) model (*see Large Autoregressive Integrated Moving Average (ARIMA) Modeling*). Most researchers who embraced the Alwan and Roberts approach assumed that the process was stationary and hence ignored the “integrated” portion of the ARIMA model, thereby reducing the analysis to somewhat simpler autoregressive moving-average (ARMA) models. We can write the general ARMA(p, q) model as shown in equation (2) [11]:

$$y_t = \mu(1 - \phi_1 - \cdots - \phi_p) + \phi_1 y_{t-1} + \cdots + \phi_p y_{t-p} + a_t - \theta_1 a_{t-1} - \cdots - \theta_q a_{t-q} \quad (2)$$

where

y_{t-i} = the quality variable of interest at time $t - i$,

$i = 0, 1, \dots, p$

μ = the mean of the process

ϕ_i = the autoregressive coefficients

θ_i = the moving-average coefficients

a_{t-j} = the random error at time $t - j$,

$j = 0, 1, \dots, q$.

The random errors are assumed to be independently and identically distributed (i.i.d.) with mean zero and variance σ_a^2 .

The application of the residual-chart approach requires the **estimation** of the autoregressive and moving-average parameters as well as the standard deviation of the error terms. Once those values are estimated, the model can be used to find fitted values of the process output, which are plotted on the common-cause chart. The difference between the actual observations and the fitted values is referred to as the *residual*, and this is what is plotted on the special-cause or residual chart.

Because of the relatively high sophistication required to fit time-series models to data, others proposed using simpler models to fit the data. For example, Montgomery and Mastrangelo [12] considered using the EWMA (*see Exponentially Weighted Moving Average (EWMA) Control Chart*) to fit the model, no matter what the “true” underlying model was. The downside of doing so was that the residuals were no longer completely independent of each other, but the reduced burden in terms of fitting the model was purported to compensate.

Residual-Chart Performance

While Alwan and Roberts [10] proposed special-cause or residual charts, they did not study the characteristics of such charts. Wardell *et al.* [5, 6] were among the first to fill the gap. By studying the run-length properties (*see Average Run Lengths and Operating Characteristic Curves*) of the special-cause chart, they showed that residual charts have poor performance when processes exhibit strong positive autocorrelation. Subsequent studies of EWMA (*see Exponentially Weighted Moving Average (EWMA) Control Chart*) and CUSUM (*see Cumulative Sum (CUSUM) Chart*) charts applied to the residuals helped [13, 14], but still suffered from the same inherent problem, which is described below. Note that the majority of comments below are true for processes displaying high levels of positive autocorrelation. For low to moderate levels of autocorrelation, residual-chart strategies fare better.

Unlike the performance of a Shewhart chart on independent data, when using residual charts to monitor processes displaying strong positive autocorrelation, if a change in the process is not detected

immediately, the probability of detecting the change subsequently becomes very small. When the shift occurs, the difference between the observed value and the fitted value is relatively large. Within a very short time, however, the statistical model or forecast absorbs the process change and the difference between the actual and fitted values becomes small again. Hence there is a very short window of opportunity over which the residual chart can detect changes in highly correlated data. If the change to the system is large, the residual chart is able to detect the shift quite easily during the short window of opportunity. For smaller changes, however, the shift is not detected during the short window and it therefore takes a very long time before the control chart signals.

Figure 1(b) shows the residual or special-cause chart applied to the residuals of the process described in the introduction. Recall that at observation 51, a shift in the mean was introduced to the simulated process. The figure reveals a spike at point 51 that is large enough to exceed the limits of the residual chart. Note that after the spike the observations settle down again and no other points fall above the limits. Such a pattern is typical of the residuals of a highly autocorrelated process when a mean shift is introduced [5]. If the mean shift is large enough, the residual chart will detect it immediately. If not, however, it typically takes a very long time to detect the shift. For this reason, some researchers [15] have applied hybrid monitoring schemes such as combinations of Shewhart charts and EWMA charts (*see Exponentially Weighted Moving Average (EWMA) Control Chart*) to improve monitoring performance. While these techniques provided improvement for low to moderate levels of positive autocorrelation, high levels of positive autocorrelation remain problematic.

For cases where the shift in the mean is small, more traditional charts (*see Exponentially Weighted Moving Average (EWMA) Control Chart; Cumulative Sum (CUSUM) Chart*) whose limits are adjusted to account for the autocorrelation are likely to have superior performance to that of the residual chart. The tendency for the statistical model to “catch up” to the actual observations makes it difficult for almost any model-based approach to discover process changes quickly. It is an enigma that has caused researchers to look for different ways to attack the problem of autocorrelation.

More Recent Approaches

The poor performance of residual charts at detecting process changes prompted many other studies to try to find charts with better detection capabilities. Some of the approaches were “incremental” changes to the two earlier types of charts, while others were more radical. The more radical approaches involved finding monitoring procedures that neither require parameter estimation nor require modeling [7, 16].

Besides looking for improved methods of monitoring autocorrelated data, studies have also expanded the contexts under which autocorrelated data are of interest. For example, a literature relating statistical monitoring and “engineering” process control has begun to grow [17] (*see Engineering Process Control; Feedback Control*). In these studies, process operators can take advantage of the autocorrelation and specific input variables to control the output variable. Residual charts can still be used in such instances, but the dynamics of the residuals are different depending on the type of control mechanisms used.

Other extensions have included the following:

- The assumption that the model (*see Large Autoregressive Integrated Moving Average (ARIMA) Modeling*) can be fit perfectly has been questioned and the effect of estimation error was studied [14, 18].
- A few researchers have included studies of other measures of interest, such as the variance [19] (*see Moving Range and R Charts; Control Charts for the Standard Deviation*), process capability [20] (*see Multivariate Charts for Variability*), and attribute data [21] (*see Control Charts for Attributes*).
- Studies of multivariate phenomena, including correlation across processes, have begun to emerge [22] (*see Multivariate Control Charts Overview; Hotelling’s T^2 Chart; Multivariate Exponentially Weighted Moving Average (MEWMA) Control Chart; Multivariate Cumulative Sum (CUSUM) Chart; Multivariate Charts for Variability; Profile Monitoring*).

Conclusions

Over the past 25 years or so we have learned a great deal about monitoring autocorrelated data.

Despite the advances, researchers have not been able to identify a “one-size-fits-all” approach that effectively monitors such data. Several important questions remain. A fundamental question that bears further investigation is whether or not we should concentrate on fitting the model to the process or the process to the model [23]. In other words, rather than spending time on trying to find the best way to fit the autocorrelated data, we may be better served by finding ways to eliminate the autocorrelation so that the data fit the traditional assumptions of SPC.

The inherent problem of residual charts makes them difficult to improve. New ways of thinking about the problem are needed. One recent approach that shows promise is the comparison of “context trees” and the use of the Kullback–Leibler statistic [16]. Other approaches that may bear fruit are nonparametric methods, visualization techniques, and integration with the change-point literature (*see Change-Point Methods*). Similarly, almost all of the activity to date has concentrated on monitoring the mean of the process. **Six Sigma** demands an understanding of and reduction of variation in the process. Financial models such as autoregressive conditional heteroscedastic (ARCH) models deal with cases where the variability shows autoregressive behavior. There may be applications of ARCH models in SPC. In any case, much remains to be done to understand the best method to monitor processes that exhibit autocorrelation.

DON G. WARDELL

Regression Control Charts

Introduction

Standard **control charts** have been widely used in process monitoring. They are often directly applied to the output of a quality characteristic. In practice, there are situations when the process output is affected by an external **covariate**, such as an incoming process variable. When the covariate takes an extreme value, the process output may appear to be in the out-of-control status even though there is actually no operation problem with the process. Intuitively, the results would be error prone in this situation when the standard control charts are directly applied. In contrast, the regression control chart proposed by Mandel [1], which combines regression analysis and control chart theory, can deal with this dilemma. The essential idea of the regression control chart is to chart the process output after it has been adjusted for the effect of the covariate.

The regression control chart has proved useful in a wide variety of applications due to its simplicity and efficiency. A least squares regression program must process the data prior to constructing the control chart. With the availability of modern computation power, the execution time of such a chart is often on the order of a few seconds. Moreover, it offers better sensitivity than a standard control chart that directly monitors the process output without taking the influence of the covariate into consideration. Among various applications, one of the most important application is for monitoring and diagnosing multistage processes because most products produced today are the result of such multistage processes. The stages are often intercorrelated in a multistage process, and the downstream variables depend on the upstream variables (see [2, 3]).

Similar concepts to regression control charts have been used for different purposes. In maximizing the sensitivity to a structured shift when performing multivariate **quality control**, Hawkins [4] proposed a control chart based on regression-adjusted variables. Hawkins [5] further modified his technique for applications in cascade processes by using only upstream observations as the independent variables in the regression adjustment. Hauck *et al.* [6] considered regression adjustment in the multivariate case. The cause-selecting control chart proposed by Zhang

[7] is an updated version of the regression control chart. Wade and Woodall [8] reviewed and extended it for simplifying the interpretation of out-of-control signals in a multistage process. Moreover, the regression control chart has a close relationship to the monitoring method used with linear profiles (*see*, e.g., [9–12]; **Profile Monitoring**). The former detects changes in the Y-intercept based on regression **residuals** while the latter monitors changes in the profile parameters, including the Y-intercept, slope and process variation. Both depend on regression analysis.

The regression control chart is a model-based monitoring procedure. In the above references, the model fitting is done by using ordinary least-squares (OLS) regression. The basic assumptions of OLS regression are normality, constant variance and independence of the observations. In some situations, these assumptions may not be always met. To remedy these assumptions, the model-building algorithm of **generalized linear models** (GLMs) can be applied. For example, Loredó *et al.* [13] incorporated the use of GLM in the regression adjustment framework for correlated data. The use of GLM for Poisson distributed counts in a regression adjustment procedure was explored in Skinner *et al.* [14, 15]. Jearkpaorn *et al.* [16, 17] discussed the use of GLM and robust GLM for a (γ -distributed response variable, respectively. Woodall [18] recently reviewed the potential applications of regression control charts in health-care and public-health surveillance in which the response variable is often non-normal.

The Regression Control Chart

Define X and Y to be the external covariate and the output characteristic of interest, respectively. The model relating X to Y can take many forms. For simplicity, the simple linear regression model

$$Y_i = \beta_0 + \beta_1 X_i + \epsilon_i \quad (1)$$

is used here for discussion. It is assumed that ϵ_i are independent and identically distributed (i.i.d.) normal variables with mean zero and variance σ^2 . In practice, the values of σ , β_0 , and β_1 are unknown and must be estimated using historical data collected from the process. We assume that a sample of n paired observations (X_i, Y_i) , are available in a set of historical data. In classical linear regression, the regressor variable, X , is assumed to be fixed. When

2 Regression Control Charts

the regressor variable is random, then the regression can be regarded as conditional on the value of the regressor (see **Least-Squares Estimation**; [19]).

Denote $\bar{X}$ and $\bar{Y}$ as the sample averages of the X and Y variables, respectively. Also, define $S_{XX} = \sum_{i=1}^n (X_i - \bar{X})^2$ and $S_{XY} = \sum_{i=1}^n (X_i - \bar{X})Y_i$. Then, the estimates of the Y-intercept, β_0 , and the slope, β_1 , can be obtained using the least-squares method (see, e.g., [20]), given by

$$\hat{\beta}_0 = \bar{Y} - \hat{\beta}_1 \bar{X} \text{ and } \hat{\beta}_1 = \frac{S_{XY}}{S_{XX}} \quad (2)$$

Denote the predicted value of Y as $\hat{Y} = \hat{\beta}_0 + \hat{\beta}_1 X$. The residual is the difference between the observed and predicted values; that is,

$$e_i = Y_i - \hat{Y}_i \quad (3)$$

The estimate of σ^2 is

$$\hat{\sigma}^2 = MSE = \frac{\sum_{i=1}^n (e_i - \bar{e})^2}{n - 2} \quad (4)$$

In the least-squares estimate, it follows that

$$\bar{e} = \sum_{i=1}^n e_i / n = 0 \quad (5)$$

The estimates $\hat{\beta}_0$, $\hat{\beta}_1$, and $\hat{\sigma}^2$ are unbiased.

The regression control chart is a Shewhart or other type of control chart applied to the regression residuals. The Shewhart regression control chart with three- σ control limits may be established as follows:

$$LCL = \bar{e} - 3\hat{\sigma}, \quad CL = \bar{e}, \quad UCL = \bar{e} + 3\hat{\sigma} \quad (6)$$

However, note that there is less accuracy in predicting a future Y value when the corresponding X value is further away from the sample mean $\bar{X}$ (see [20]). To account for this, it has been suggested that the parallel limits in equation (6) be revised to the prediction limits [8]

$$LCL = \bar{e} - k\hat{\sigma}_e, \quad CL = \bar{e}, \quad UCL = \bar{e} + k\hat{\sigma}_e \quad (7)$$

The variable

$$\hat{\sigma}_e = \sqrt{MSE \left(1 + \frac{1}{n} + \frac{(X_0 - \bar{X})^2}{S_{XX}} \right)} \quad (8)$$

is the **standard error** of the prediction for a given future observation of $X = X_0$. The constant multiplier, k , can be chosen as $k = t(\alpha/2; n - 2)$, where $t(\alpha/2; v)$ is the upper $\alpha/2$ percentile of the Student's t distribution with v **degrees of freedom**. Although the residuals are dependent due to parameter **estimation**, the simulation study performed by Wade and Woodall [8] shows that this choice can maintain an approximate false-alarm rate of α .

An Example

For illustration, the example on the ABCD Post Office Department in [1] is used here. The variables measured are X = the number of pieces of mail (in millions) handled in a four-week period and Y = the number of man hours (in thousands) used. Table 1 summarizes the data. The first 26 data points are used to estimate the regression parameters and calculate

Table 1 Data on mail processing hours and volume for the ABCD post office

Number	X	Y	Number	X	Y	Number	X	Y	e
1	157	572	14	154	569	27	162	623	31
2	161	570	15	157	564	28	174	664	32
3	168	645	16	164	573	29	171	664	42
4	186	645	17	188	667	30	182	680	21
5	183	645	18	191	700	31	175	650	14
6	184	671	19	180	765	32	169	582	-34
7	268	1053	20	270	1070				
8	180	675	21	180	637				
9	175	670	22	172	650				
10	193	710	23	184	655				
11	184	656	24	179	665				
12	179	640	25	169	599				
13	164	599	26	160	605				

the control limits while the last six are used for future monitoring purposes. As shown by [1], observations 7, 19, and 20 are abnormal. Therefore, they are excluded from the computations used to establish a preliminary control chart.

After excluding the three abnormal points, the fitted relationship between X and Y is

$$\hat{Y} = 50.44 + 3.345X \quad (9)$$

with

$$\hat{\sigma} = 18.92 \quad (10)$$

The next step is to compute the predicted Y values and the residuals for the last six observations, which are also given in Table 1. Given the results with $n = 23$, $S_{XX} = 3097.7$ and $\bar{X} = 174.4$ obtained from the revised data set (i.e., observations 7, 19, and 20 are removed), $\hat{\sigma}_e$ can be computed and then the prediction limits can be established.

For example, consider $\alpha = 0.05$ and the value of k is then set as $k = t(0.025; 21) = 2.08$. Figure 1(a) plots the regression control chart, and an out-of-control signal is triggered at observation 29. This signal is due to hiring a large number of inexperienced employees, as explained by Mandel [1]. For comparison, Figure 1(b) plots a Shewhart chart on the Y variable (i.e., manhours used). The control limits are placed at two estimated standard deviations of Y from the center line (i.e., $\bar{Y} \pm 2\hat{\sigma}_Y = 634 \pm 2 \times 44.78$), which can approximately provide a false-alarm rate of 5%. The Y chart in Figure 1(b) does not indicate an out-of-control situation. This example illustrates that better sensitivity on the regression control chart

can be achieved due to the adjustment for the effect of the external covariate compared to standard control charts.

Concluding Remarks

The regression control chart is a useful statistical process control (SPC) tool in many applications, including monitoring and diagnosing multistage processes. Compared with standard control charts, it may provide better sensitivity to changes in process output. Moreover, the regression control chart has the ability to distinguish between incoming and outgoing problems when it is used in combination with a control chart on the incoming variable. This facilitates the interpretation issue of an out-of-control signal in multistage process monitoring. In contrast, a multivariate control chart cannot make this distinction (see **Multivariate Control Charts Overview**).

An important step of the regression control chart is to estimate the model parameters from a historical data set. The parameter estimation leads to the dependence of the regression residuals although the observations on the output are originally independent. This dependency in turn causes deterioration of the performance of the chart, which has been investigated by Shu *et al.* [21, 22]. The minimum sample size required for the regression control chart to perform like the chart with known parameters is shown to be considerably larger than expected. For this reason, the minimum sample-size requirement may not be satisfied in real situations. Shu *et al.* [21] discussed some remedies for this problem without detailed

Figure 1 (a) A regression control chart and (b) a control chart for man hours

investigations, although much more work is needed on this issue.

Great efforts have been devoted to phase II methods of regression control charts while relatively less attention has been given to phase I analysis. In practical applications, it is often assumed that the historical data collected from the process is in control or reasons for assignable causes can be identified. However, there could be **outliers** in the data. In the existing phase I methods for a regression control chart, the control limits established to identify outliers are based purely on rules of thumb. The traditional use of three- σ limits would produce a false-alarm rate that would be very different from the desired rate of 0.0027. How to maintain the exact type I error probability in phase I of a regression control chart remains an important issue that requires more discussion. One possible remedy is to use the self-starting control chart [23, 24].

Control Charts, Nonparametric

Introduction

Distribution of Chance Causes

In statistical process control (SPC), the pattern of chance causes is usually assumed to follow some parametric distribution (such as the normal). The charting statistic and the control limits depend on this assumption and as such the properties of these **control charts** are “exact” only if this assumption is satisfied. However, the chance distribution is either unknown or far from being normal in many applications and consequently the performance of standard control charts can be highly affected in such situations. Thus, there is a need for some easy to use, flexible and robust control charts that do not require normality or any other specific parametric model assumption about the underlying chance distribution. Distribution-free or nonparametric control charts can serve this broader purpose.

Nonparametric or Distribution-Free

The term *nonparametric* is not intended to imply that there are no parameters involved, in fact, quite the contrary. While the term *distribution-free* seems to be a better description of what we expect from these charts, that is, they remain valid for a large class of distributions, nonparametric is perhaps the term more often used. In the statistics literature, there is now a rather vast collection of **nonparametric tests** and **confidence intervals**, and these methods have been shown to perform well compared to their normal theory counterparts. Remarkably, even when the underlying distribution is normal, the efficiency of some nonparametric methods relative to the corresponding (optimal) normal theory methods can be as high as 0.955 (see, e.g., Gibbons and Chakraborti [1]). In fact, for some heavy-tailed distributions like the double exponential, nonparametric tests can be more efficient. It may be argued that nonparametric methods will be “less efficient” than their parametric counterparts when one has a complete knowledge of the process distribution for which that parametric method was specifically designed. However, the reality is

that such information is seldom, if ever, available in practice. Thus, it seems natural to develop and use nonparametric methods in SPC and the quality practitioners will be well advised to have these techniques in their tool kits.

We mostly discuss univariate nonparametric control charts designed to track the location of a continuous process; very few charts are available for scale. The field of multivariate control charts (*see **Multivariate Control Charts Overview***) is interesting and the body of literature on nonparametric multivariate control charts is growing. However, in our opinion, it has not yet reached a critical mass and a discussion on this topic is better postponed for the future.

Nonparametric Control Charts

Chakraborti, van der Laan, and Bakir (hereafter CVB) [2] provided a systematic and thorough account of the nonparametric control charts literature. A nonparametric control chart is defined in terms of its in-control run length distribution. If the in-control run length distribution of a control chart is the same for every continuous distribution, the chart is called *nonparametric* or *distribution-free*. CVB summarized the advantages of nonparametric control charts as follows: (a) simplicity, (b) no need to assume a particular parametric distribution for the underlying process, (c) the in-control run length distribution is the same for all continuous distributions (the same is true for the false alarm rate (FAR) and the in-control **average run length** (ARL_0)), (d) more robust and **outlier** resistant, (e) more efficiency in detecting changes when the true distribution is markedly non-normal, particularly with heavier tails, and (f) no need to estimate the variance to set up charts for the location parameter. It is emphasized that from a technical point of view most nonparametric procedures require the population to be continuous in order to be distribution-free and thus in an SPC context we consider the so-called variables control charts.

Terminology and Formulation

Two important problems in usual SPC are monitoring the process mean (*see **Control Charts for the Mean***) and/or the process standard deviation (*see **Control Charts for the Standard Deviation***). In the nonparametric setting, we consider, more generally, monitoring the center or the location parameter

and/or a scale parameter of a process. The location parameter represents a typical value and could be the mean or the median or some other percentile of the distribution; the latter two are especially attractive when the underlying distribution is expected to be skewed. When the underlying distribution is symmetric, the mean and the median are the same and any of these can serve as a measure of the typical. Also in the nonparametric setting, the processes are often implicitly assumed to follow (a) a location model, with a cdf $F(x - \theta)$, where θ is the location parameter or (b) a scale model, with a cdf $F(x/\tau)$, where $\tau (> 0)$ is the scale parameter. Even more generally, one might consider (c) the location-scale model with cdf $F\{(x - \theta)/\tau\}$, where θ and τ are the location and the scale parameter, respectively. Under these model assumptions, the problem is to track θ or τ (or both), based on random samples or subgroups taken (usually) at equally spaced time points. In the usual (parametric) control charting problems F is assumed to be the cdf Φ of the standard **normal distribution** whereas in the nonparametric setting, for variables data, F is some unknown continuous cdf. Although the location-scale model seems to be a natural model to consider paralleling the normal case with mean and variance, both unknown, most of the currently available literature deals mainly with the location model.

As we noted earlier, a comprehensive survey of the literature until about 2000 can be found in CVB. Here, we briefly mention some of the key contributions and ideas and a few of the more recent developments in the area; the literature on nonparametric methods continues to grow at a rapid pace. Most nonparametric charts have been developed for phase II applications. There are generally two phases in SPC. In phase I (also called the *retrospective phase*), typically, preliminary analysis is done which includes planning, administration, data collection, data management, exploratory work including graphical and numerical analysis, goodness-of-fit analysis, and so on, to ensure that the process is in-control. This means that the process is operating at or near some acceptable target value along with some natural variation and no special causes of concern are present. Once this is ascertained, SPC moves to the next phase, phase II, (or the *prospective phase*), where the control limits and/or the estimators obtained in phase I are used for process monitoring based on new samples of data. When the underlying parameters of the process distribution are known or specified, this

is referred to as the *standard(s) known* case and is denoted case K. On the contrary, if the parameters are unknown and need to be estimated it is typically done in phase I, with in-control data. This situation is referred to as the *standard(s) unknown* case and is denoted case U.

There are three main classes of control charts: the Shewhart chart, the cumulative sum (CUSUM; *see Cumulative Sum (CUSUM) Chart*) chart, and the exponentially weighted moving average (EWMA; *see Exponentially Weighted Moving Average (EWMA) Control Chart*) chart and their refinements. Relative advantages and disadvantages of these charts are well documented (see, e.g., Montgomery [3]) in the literature. Analogs or types of these charts have been considered in the nonparametric setting. We describe some of the charts under each of the three classes.

Shewhart-Type Charts

Shewhart-type charts are the most popular in practice because of their simplicity, ease of application, and the fact that these versatile charts are quite efficient in detecting moderate-to-large shifts. Both one-sided and two-sided charts are considered. The one-sided charts are more useful when only a directional shift (higher or lower) in the median is of interest. The two-sided charts on the other hand are typically used to detect a shift or change in the median in any direction.

Case K.

Charts for Location.

Sign control charts. Sign control charts are based on the well-known sign test. The sign test is one of the simplest and most broadly applicable nonparametric tests (see, e.g., Gibbons and Chakraborti [1]) that can be used to test hypotheses (or find confidence intervals) on the median (or any specified percentile) of a continuous population. Suppose that the median of a continuous process needs to be maintained at a specified value θ_0 . Amin *et al.* [4] presented Shewhart-type nonparametric charts for this problem using what are called *within group sign* statistics. This is called the *SN chart*. Let $X_{i1}, X_{i2}, \dots, X_{in}$ be the i th ($i = 1, 2, \dots$) sample (or subgroup) of

independent observations of size $n > 1$. A control chart is a graphic consisting of values of a plotting (or charting) statistic and the associated control limits. The plotting statistic for the SN chart is $SN_i = \sum_{j=1}^n \text{sign}(X_{ij} - \theta_0)$. In order to find the control limits and study chart performance, the distribution of SN_i is necessary. This can be most easily obtained using the relationship $SN_i = 2T_i - n$, where T_i is the usual sign test statistic, which is a count of the number of sample observations greater than or equal to θ_0 . Since the in-control distribution of T_i is binomial with parameters n and $1/2$, it follows that the in-control distribution of SN_i is symmetric about 0 and hence the control limits and the centerline of the two-sided nonparametric Shewhart-type sign chart are: $UCL = c$, $CL = 0$, $LCL = -c$, where c is some positive integer between 0 and n . If the plotting statistic SN_i falls between the control limits, the process is declared to be in-control, whereas if the plotting statistic SN_i falls on or outside one of the control limits, that is, if $SN_i \leq -c$ or $SN_i \geq c$, the process is considered to be out-of-control. The charting constant c is typically obtained for a specified ARL_0 , which, in case K, is equal to the reciprocal of the nominal FAR, α . Thus, using the symmetry of the binomial distribution, c is the smallest integer such that $P_{\theta_0}(SN_i \geq c) \leq \alpha/2$. For example, using Table G of Gibbons and Chakraborti [1] we give some $P_{\theta_0}(T \geq t)$ values in Table 1 that may be considered “small” in a SPC context. The charting constant c is obtained using $c = 2t - n$. For example, for $n = 5$ we get $t = 5$ and thus $c = 5$ for a FAR of $2(0.0312) = 0.0624$ and this is the lowest FAR achievable. However, for $n = 10$ the FAR drops to 0.0020 if $c = 10$.

Looking at the achievable FAR values shown in the second row of Table 1, we see that unless the

sample size n is 10 or more, the sign chart could be somewhat unattractive (from an operational point of view) in SPC applications, where one often stipulates a FAR as small as 0.0027. On the other hand, the sign chart is the simplest of nonparametric charts that works under minimal assumptions. In fact, from the **hypothesis testing** literature, it is known that the sign test (and so the chart) is more robust and efficient when the chance distribution is symmetric like the normal but with heavier tails such as the double exponential.

Example 1 We illustrate the Shewhart-type sign chart using a set of data from Montgomery [3, Tables 5.1 and 5.2] on the inside diameters of piston rings manufactured by a forging process. A part of this data, 15 prospective samples (Table 5.2) each of five observations, is used here. The rest of the data (Table 5.1) will be used later. We assume that the underlying distribution is symmetric with a known median $\theta_0 = 74$ mm. Table 2 shows the SN_i values.

The sign chart is shown in Figure 1 with control limits at ± 5 . Observations 12, 13 and 14 lie on the upper control limit (UCL) which indicates that the process is out-of-control starting at sample 12. It appears most likely that the process median has shifted upwards from the in-control value of 74 mm.

Control charts are often compared on the basis of various characteristics of the run length distribution, such as the ARL. One prefers a longer ARL_0 and a shorter out-of-control ARL under a shift. Amin *et al.* [4] compared the ARL of the classical Shewhart $\bar{X}$ chart and the Shewhart-type sign chart for various shift sizes and underlying distributions. Generally speaking, when the distribution is either asymmetric

Table 1 FAR and ARL_0 of a sign control chart for various values of n and t

n	5	6	7	8	9	10
t	5	6	7	8	9	10
$P_{\theta_0}(T \geq t)$	0.0312	0.0156	0.0078	0.0039	0.0020	0.0010
FAR (α)	0.0624	0.0312	0.0156	0.0078	0.0040	0.0020
ARL_0	16.00	32.00	64.00	128.00	256.00	512.00

Table 2 Sign statistics (SN_i) for the piston-ring data in Montgomery [3]

SN_i	2	1	-4	3	0	3	3	-1	3	4	1	5	5	5	4

Figure 1 Shewhart-type sign control chart for Montgomery [3] piston-ring data

or symmetric with heavy tails, the sign charts are more efficient while the reverse is true for the normal and the normal-like distributions with light tails. However, one practical advantage of the sign charts (and of all nonparametric charts) is that the FAR (and the ARL_0) remains the same for all continuous distributions. This is not true for any parametric chart designed for a specific distribution, including the Shewhart $\bar{X}$ chart.

Signed-Rank Control Charts. A second popular nonparametric test for the median of a continuous and symmetric population is the signed-rank (SR) (or the Wilcoxon SR) test. The SR test is more powerful than the sign test but while the sign test is applicable for all continuous distributions, the assumption of symmetry must be made, in addition, for the SR test. Moreover, the sign test applies to all **percentiles** but the SR test is proposed only for the median. Details about the SR test can be found, for example, in Gibbons and Chakraborti [1]. Bakir [5] proposed a Shewhart-type nonparametric control chart based on the SR test statistic. This is called the *SR chart*. Let $|X_{i1} - \theta_0|, |X_{i2} - \theta_0|, \dots, |X_{in} - \theta_0|$ denote the absolute values of the deviations (from θ_0) for the i th subgroup and let R_{ij} denote the rank of $|X_{ij} - \theta_0|$ among the n absolute deviations. The plotting statistic of the SR chart is given by

$SR_i = \sum_{j=1}^n \text{sign}(X_{ij} - \theta_0) R_{ij}, i = 1, 2, 3, \dots$. Note that the statistic SR_i is the difference between the sum of the ranks (of the absolute values) corresponding to the positive and the negative deviations, respectively. This is linearly related to the better-known Wilcoxon SR statistic W^+ through the relationship $SR = 2W^+ - (n(n+1)/2)$, where W^+ is the sum of the ranks of the absolute values corresponding to the positive deviations. Since W^+ is known to be distribution-free [1] so is SR_i and the SR chart. The in-control distribution of SR_i is symmetric about 0, so choosing $LCL = -UCL$ seems reasonable and like the Shewhart-type sign chart this results in a (visually appealing) symmetric control chart. Thus as in the case of the sign chart, the control limits and the centerline of the two-sided Shewhart-type SR chart are: $UCL = d, CL = 0, LCL = -d$, where d is some positive integer. If the plotting statistic SR_i for some subgroup falls on or outside of the control limits, the process is declared to be out-of-control at that subgroup. Otherwise, the process is deemed to be in-control. The constant d is found so that a specified FAR (or equivalently an ARL_0) is attained. Bakir [5] calculated the FAR (p_0^+) and the in-control average run length (ARL_0^+) of the upper *one-sided* Shewhart-type signed-rank (SR^+) control chart (process out-of-control if $SR_i \geq UCL = d$) by using the null distribution of the Wilcoxon SR statistic. For

the two-sided SR chart, the FAR and the ARL_0 can be obtained from $p_0 = 2p_0^+$ and $ARL_0 = ARL_0^+/2$, respectively.

The SR chart competes well with the traditional Shewhart $\bar{X}$ chart in case of the normal distribution and is more efficient in case of a heavy-tailed distribution such as the double exponential or the Cauchy. However, the FAR values for the chart are too high (in other words the ARL_0 values are too short) unless the subgroup size n is large, say in the neighborhood of 20. This may not be a problem in applications where $n = 20$ is still considered “small”, but $n = 20$ is not typical in **quality control** applications and thus such charts, like the SN charts, can be somewhat unappealing from a practitioner’s point of view. One way to remedy this problem is to use some signaling rules to enhance the sensitivity of the charts. We consider this next.

Runs Rules, Signaling Rules, and Nonparametric Charts. A “run” is generally used to describe a sequence or succession of objects or observations of the same type in an ordered sequence. For example, if we have a signal for the first time on the fifth sample, there must have been a total of four no signals before the first signal from the first four samples and this constitutes a run of four no signals. In the SPC setting, runs have been typically employed to increase the sensitivity of control charts. Various rules or “tests for special causes” have been considered in the literature for parametric control charts; see for example, the rules associated with the Shewhart control chart in Nelson [6] and in the Western Electric Handbook [7]. See also the discussion in Montgomery [3].

Sign Control Charts with Warning Limits. In the nonparametric SPC literature, Amin *et al.* [4] considered Shewhart-type sign charts with warning limits and runs rules. The two-sided chart with action (control limits) at $\pm a_2$ is defined as follows. The centerline is 0. The warning limits are drawn at $\pm w_2$. A signal is given if r consecutive plotting statistics fall in the region $[w_2, a_2)$ or $(-a_2, -w_2]$, or if any plotting statistic falls outside $\pm a_2$. The average run length can be calculated from the average run lengths for the two one-sided charts. First, using results in Page [8], it can be shown that the ARL_0 of the one-sided (upper or positive direction) chart with warning limit at $w_2 (0 \leq w_2 \leq a_2)$ and control limit (action

limit) at a_2 is given by

$$L_0^+(\theta) = \frac{1 - p_1^r}{1 - p_1 - p_0(1 - p_1^r)} \quad (1)$$

where $p_0 = P(SN_i < w_2|\theta)$, $p_1 = P(w_2 \leq SN_i < a_2|\theta)$. Similarly, the ARL_0 of a one-sided (lower or negative direction) chart with warning limit at $-w_2$ and control limit (action limit) at $-a_2$, $L_0^-(\theta)$, can be found by replacing p_0 and p_1 by q_0 and q_1 where $q_0 = P(SN_i > -w_2|\theta)$ and $q_1 = P(-a_2 < SN_i \leq -w_2|\theta)$. The ARL_0 for the two-sided chart can then be obtained using a result in Roberts [9],

$$\frac{1}{L_0(\theta)} = \frac{1}{L_0^-(\theta)} + \frac{1}{L_0^+(\theta)} \quad (2)$$

In practice some observations can be tied with the specified median. If the number of such cases is small (relative to n) one can drop the tied cases and reduce n accordingly. On the other hand, if the number of ties is large, more sophisticated analysis might be necessary.

These procedures cannot be meaningfully illustrated using the data of Example 1 because the sample size $n = 5$ used there is too small. It may be noted that the highest possible $L_0(\theta)$ values for the basic (without warning limits) two-sided sign chart can be seen to be 2^{n-1} . Thus, achievable values of $L_0(\theta)$ are too small for practical use, unless n is about 10. In Table 3, the charting constants, i.e. the warning and action limits, are shown, along with the achieved ARL values, for the in-control and one out-of-control case. We compare three sign charts, two with warning limits and one without. The ARL values for the two-sided sign chart, without the warning limits, are shown in each case, within parentheses, for reference.

It is seen that adding warning limits to a control chart decreases its average run length. For example, adding a warning limit at 7 to the basic sign chart with an action limit at 10 decreases the ARL_0 approximately 59% (from 512 to 208.97), when $r = 2$, 7% (from 512 to 476.03) when $r = 3$ and 0.002% (from 512 to 511.99) when $r = 6$, respectively. The out-of-control average run length is decreased by approximately 79% (from 162.6 to 35.03) when $r = 2$, 36% (from 162.6 to 103.28) when $r = 3$, and 0.26% (from 162.6 to 162.17) when $r = 6$, respectively. Note that although the out-of-control average run length is reduced significantly (which means a quicker detection of shift) by the addition of warning

6 Control Charts, Nonparametric

Table 3 In-control ARL values for the two-sided sign chart with and without warning limits for $n = 10$

	$r = 2$	$r = 3$	$r = 6$
$w = 7$ and $a = 10$			
$p = 0.5$ (in-control)	208.97 (512)	476.03 (512)	511.99 (512)
$p = 0.6$ (out-of-control)	35.03 (162.6)	103.28 (162.6)	162.17 (162.6)
$w = 7$ and $a = 8$			
$p = 0.5$ (in-control)	42.86 (46.55)	46.37 (46.55)	46.55 (46.55)
$p = 0.6$ (out-of-control)	16.37 (20.82)	20.16 (20.82)	20.82 (20.82)

limits, the ARL_0 is also reduced significantly. This poses a dilemma in practice, since it is desirable to have a high ARL_0 or a low FAR, so one would need to strike a balance. One possibility is to use warning limits closer to the action limits. For example, from the second panel of Table 3, we see that adding a warning limit at 7 to the sign chart with an action limit of 8, decreases the ARL_0 by only 8% (from 46.55 to 42.86) when $r = 2$ and has little effect on ARL_0 when r is reasonably large. Amin *et al.* [4] concluded that for the upper one-sided Shewhart-type sign chart, introduction of warning limits will have little effect on the ARL_0 , but can significantly reduce the out-of-control ARL for small shifts in θ when the warning limits are chosen close to the action limits and r is reasonably large. Similar conclusions are expected to hold for two-sided charts.

In addition to defining warning limits or zones on control charts, runs have been used to define signaling rules in conjunction with usual control limits. The rules considered include the following: A process is declared to be out-of-control when (a) a single point (charting statistic) plots outside the control limit(s) (1-of-1 rule), (b) k consecutive points (charting statistics) plot outside the control limit(s) (k -of- k rule), or (c) k of the last w points (charting statistics) plot outside the control limit(s) (k -of- w rule). Rule (a) is the simplest and is the most frequently used in the literature. Thus, the 1-of-1 rule corresponds to the usual control chart, where a signal is given when a plotting statistic falls outside the control limit(s). Rules (a) and (b) are special cases

of rule (c); rules (b) and (c) have been used in the context of supplementing the Shewhart charts with warning limits and zones.

Signed-Rank Control Charts with Runs-Type Signaling Rules. Chakraborti and Eryilmaz [10] considered simple alternatives to Bakir's [5] class of nonparametric charts, using the SR statistic but incorporating runs rules of the type discussed above to define new signaling rules. These are called the 2-of-2 DR and the 2-of-2 KL charts, both based on the signed-rank statistic SR. The 2-of-2 KL chart signals, for example, when two of the most recent SR statistics both fall either above or below the control limits. The 2-of-2 DR chart is similar, here a signal is indicated when the SR statistics fall either both above or both below or one above (below) and the next one below (above) the control limits. It is shown that the new charts are nonparametric, have much smaller FAR (and thus longer ARL_0) than the 1-of-1 SR chart of Bakir. Moreover, the new charts have better out-of-control performance for some distributions like the normal and the Cauchy. We illustrate these procedures using the same data used in our earlier example.

Example 2 Table 4 shows the signed-rank (SR) statistics for the 15 samples.

The symmetric two-sided control limits for the SR charts are obtained from Chakraborti and Eryilmaz [10]. For $n = 5$, the control limits for the 1-of-1 (Bakir's chart), the 2-of-2 DR and the 2-of-2 KL charts, based on the SR statistic, are set at ± 15 . These

Table 4 Signed-rank statistics (SR_i) for the piston-ring data in Montgomery [3]

Sample number: i	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15
SR_i	8	4	-14	7	-3	9	10	-6	12	14	4	15	15	15	14

Figure 2 Shewhart-type signed-rank control chart for Montgomery [3] piston-ring data

yield FAR values 0.0626, 0.0039, and 0.0019, respectively. If the control limits were taken to be ± 13 , the FAR would have been much higher: 0.125, 0.0156, and 0.0078, respectively. Although the control limits are the same, namely ± 15 , the signaling rules are quite different operationally and the performance of the resulting charts turn out to be quite different. The 1-of-1 chart signals when the first SR statistic falls outside either of the two control limits; the 2-of-2 KL chart signals when, for the first time, two consecutive SR statistics fall either above or below the two control limits, while the 2-of-2 DR chart signals when, for the first time, two consecutive SR statistics fall outside the control limits, either both above or both below, or one above and the next below, or one below and the next above. On the performance side, note that the 1-of-1 SR chart has a FAR of 0.0626 and an ARL_0 of only 16. Thus many more false alarms will be signaled by this chart leading to a possible loss of time and resources. Compared to that, the 2-of-2 KL chart has a FAR of 0.0019 and an ARL_0 of 526.34, whereas the 2-of-2 DR chart has a FAR of 0.0039 and an ARL_0 of 271.15. Thus both of these run-rule-enhanced charts provide reasonable and practical FARs and can be used in practice, depending on the type of shift one expects.

Figure 2 shows the two-sided control chart with

the symmetric control limits and a plot of the SR statistics.

Thus the DR and KL 2-of-2 SR charts both signal at sample 13, indicating a most likely upward shift in the process median. The 1-of-1 SR chart, on the other hand, signals earlier at sample 12, but note the much higher FAR of 0.0626 (and correspondingly a much lower and less desirable ARL_0 , 15.97) associated with this chart. It is interesting to note that, as shown in Montgomery [3], for these data the Shewhart $\bar{X}$ chart indicates a shift in the mean at sample 11 for these data. However, the key difference is that an application of the Shewhart chart can raise several questions such as the form of the underlying distribution (small $n = 5$), and more importantly about the in-control (stable) performance of the chart in terms of the FAR (or the ARL_0), since it is known that the in-control performance of the Shewhart $\bar{X}$ chart is not robust in typical quality control applications. Compared to this, the proposed nonparametric charts provide a more generally applicable alternative monitoring scheme with a known (stable/robust) in-control performance and a better or equal out-of-control performance.

Charts for Scale. Amin *et al.* [4] also considered a Shewhart-type nonparametric sign chart for the variability based on counts that fall between or outside some prechosen **quartiles**, such as the first and the

third, that are assumed known. They compared their chart to the chart based on S^2 and suggested that the chart based on S^2 is more efficient, but of course the chart based on S^2 is not distribution-free. The overall conclusion is that the nonparametric charts provide a useful alternative to the standard charts when normality is in doubt. More work on nonparametric charts for scale or dispersion will be useful.

In general, control charts (and particularly nonparametric control charts) are simpler to use in case K. In practice, however, the process parameters are sometimes unknown or unspecified. We refer to this situation as case U; a phase I analysis is typically used here first to establish the process in-control and then control limits are calculated from a set of data from the in-control process having estimated any unknown parameters. Such data are referred to as *reference data*. The estimated control limits are then used for prospective process monitoring in phase II. We now discuss some nonparametric control charts useful in case U.

Case U.

Charts for Location. Janacek and Meikle [11] proposed a phase II nonparametric control chart useful in case U. The control limits of this chart are given by two selected order statistics of a phase I reference sample and the charting statistic is the median M_i of the phase II samples taken sequentially. More details are given below.

Precedence Control Charts. Chakraborti, van der Laan, and van de Wiel (hereafter CVV) [12] generalized the work of Janacek and Meikle [11]. They considered using some order statistic of a phase II sample as the charting statistic and control limits constructed from a phase I reference sample. Their work involves a class of two-sample nonparametric statistics, called *precedence statistics* and their Shewhart-type charts are called *precedence charts*. Assume that a reference sample of size m is available from an in-control process. The control limits of the precedence chart are given by two reference sample order statistics, say, $LCL = X_{a:m}$ and $UCL = X_{b:m}$, where $1 \leq a < b \leq m$. The plotting statistic $Y_{j:n}^h$ is the j th order statistic from the h th phase II sample of size n . The plotting statistic is taken to be the median for subsequent illustration but, in fact, it can be any percentile of the phase II sample. CVV provided

recommendations and tables for the implementation of precedence charts and examined the chart performance in terms of the ARL. The overall conclusion is that the Shewhart-type precedence charts are much more robust than their parametric counterparts. The precedence chart, being nonparametric, has the in-control robustness property (such as the same ARL_0 or the FAR for all continuous distributions), whereas as we noted earlier, the Shewhart $\bar{X}$ (and other parametric charts) can suffer serious degradations when the underlying distribution is not as assumed (normal).

Precedence Charts with Signaling Rules. Chakraborti *et al.* [13] considered enhancing the precedence charts with the 2-of-2 type signaling rules. We illustrate these procedures using the piston-ring data from Montgomery [3].

Example 3 Here we use the data given in Table 5.1, of Montgomery [3]. These are the 25 retrospective or phase I samples, each of size five that were collected when the process was thought to be in-control. The traditional Shewhart $\bar{X}$ and R charts provide no indication of an out-of-control condition, so these “trial” limits were adopted for use in on-line process control. These data are considered to be phase I reference data.

In order to implement the control charts, the charting constants are needed. Generally, one finds the chart constants so that a specified ARL_0 , such as 500, or 370, is obtained. For the precedence type charts, symmetric control limits are used so that $b = m - a + 1$ and only one charting constant a (integer, ≥ 1) needs to be found. Possible control limits for the three charts are shown in Table 5 for $m = 125$, $n = 5$ and $j = 3$, along with the corresponding FAR and ARL_0 values. The basic Shewhart-type precedence chart is referred to as the *1-of-1 chart*.

Thus, for an ARL_0 of 500, one can take $a = 7$ and $b = 119$ so that the control limits for the 1-of-1 precedence chart are the 7th and the 119th ordered values of the reference sample. Thus $LCL = X_{7:125} = 73.984$ and $UCL = X_{119:125} = 74.017$, which yield an in-control average run length of 413.80 and a FAR of 0.0044. A plot of the medians for the 1-of-1 chart is shown in Figure 3. It is seen that the 1-of-1 precedence chart signals on the 12th sample in the prospective phase.

Table 5 In-control average run length (ARL_0), false alarm rate (FAR), and chart constant (a) for the 1-of-1, 2-of-2 DR, and 2-of-2 KL precedence charts when $m = 125$, $n = 5$, and $j = 3$

1-of-1			2-of-2 DR			2-of-2 KL		
a	ARL_0	FAR	a	ARL_0	FAR	a	ARL_0	FAR
5	1315.98	0.001865	19	464.38	0.004020	19	819.47	0.002355
6	695.09	0.002948	20	344.73	0.005195	20	608.81	0.003019
7	413.80	0.004358	21	260.69	0.006627	21	460.54	0.003823
8	267.40	0.006164	22	200.46	0.008356	22	354.09	0.004788

**Figure 3** 1-of-1 phase II precedence chart for the Montgomery [3] piston-ring data

For the 2-of-2 DR chart, take $a = 19$ so that $b = 125 - 19 + 1 = 107$ and the resulting limits, $LCL = X_{19:125} = 73.992$ and $UCL = X_{107:125} = 74.012$, yield an ARL_0 and FAR of 464.38 and 0.0040, respectively. Note, however, that if one chooses $a = 20$ so that $b = 106$, the control limits are $LCL = X_{20:125}$ and $UCL = X_{106:125}$ and the ARL_0 decreases to 344.73, whereas the FAR slightly increases to 0.0052. The 2-of-2 DR chart is shown in Figure 4.

Finally, for the 2-of-2 KL chart take $a = 21$ so that $b = 125 - 21 + 1 = 105$ so that $LCL = X_{21:125} = 73.992$ and $UCL = X_{105:125} = 74.011$, and this yields an ARL_0 of 460.54 and a FAR of 0.0038, respectively. This 2-of-2 KL chart is almost identical to the chart in Figure 4 and is thus omitted. Both the 2-of-2 DR and KL charts signal on the 10th sample in the

prospective phase. Note, however, that the achieved FAR values for all three charts are much larger than the nominal FAR of 0.0027.

Mann–Whitney–Wilcoxon Control Charts. While the precedence chart is a step in the right direction, the precedence test is not the most popular or the most powerful of nonparametric two-sample tests. That honor goes to the Mann–Whitney (MW) test (see for example, Gibbons and Chakraborti, 2003 [1]). The MW test (equivalent to the popular Wilcoxon rank-sum test) is a well-known nonparametric competitor of the two-independent-sample t -test. The test is known to be more powerful than the precedence test for light tailed distributions and hence MW charts are expected to be more efficient. Of course,

Figure 4 2-of-2 phase II DR chart for the Montgomery [3] piston-ring data

the MW chart is also distribution-free and therefore has the same in-control robustness advantage as the precedence chart, that its in-control distribution is completely known. Park and Reynolds [14] considered control charts for monitoring the location parameter of a continuous process in case U. One of the special cases of their charts is the MW chart based on the well-known Mann–Whitney–Wilcoxon (MWW) statistic. The control limits of these charts are established using phase I reference data. However, they only considered properties of this chart when the reference sample size approaches infinity. Chakraborti and van de Wiel [15] considered the Shewhart-type MW chart, studied its properties, and provided tables for its implementation. These authors show that in some cases the MW chart is more efficient than the precedence chart.

Example 4 For the piston-ring data with $m = 125$ and $n = 5$, Chakraborti and van de Wiel [15] found the upper and the lower control limits of the Shewhart-type MW chart to be 540 and 85, respectively, for a specified $ARL_0 = 400$. The 15

phase II samples and the reference sample lead to 15 MW statistics shown in Table 6 (read from left to right and to left) and the MW control chart is shown in Figure 5.

It is seen that all but three of the test groups, 12, 13 and 14 are in-control. The conclusion from the MW chart is that the medians of test groups 12, 13 and 14 have shifted to the right in comparison with the median of the in-control distribution, assuming that G is a location shift of F . It may be noted that the Shewhart $\bar{X}$ chart shown in Montgomery [3] led to the same conclusion with respect to the means. Of course, the advantage with the MW chart (and with any nonparametric chart) is that it is distribution-free, so that regardless of the underlying distribution, the in-control ARL of the chart is roughly equal to 400 and there is no need to worry about non-normality, as one must for the $\bar{X}$ chart. The distribution-free 1-of-1 precedence chart for this data for an $ARL_0 = 400$ is found to be $LCL = 73.982$ and $UCL = 74.017$ for an attained $ARL_0 \approx 414.0$. Consequently, the precedence chart declares the 12th and the 14th

Table 6 Phase II MW statistics for the piston-ring data in Montgomery [3]

429.0	333.0	142.5	370.5	241.5	410.5	393.0	240.5
471.0	486.0	340.5	561.0	575.5	601.5	484.5	–

Figure 5 1-of-1 phase II MW chart for the Montgomery [3] piston-ring data

groups to be out-of-control but not the 13th group (see Figure 3), unlike the MW and the Shewhart chart. This is not entirely surprising since the MW test is generally more powerful than the precedence test.

CUSUM-Type Charts

While the Shewhart-type charts are the most widely known and used control charts in practice because of their simplicity and global performance, other classes of charts, such as the CUSUM charts (*see Cumulative Sum (CUSUM) Chart*) are useful and sometimes more naturally appropriate in the process control environment in view of the sequential nature of data collection. These charts, typically based on the cumulative totals of a plotting statistic, obtained as data accumulate, are known to be more efficient for detecting certain types of shifts in the process. The normal theory CUSUM chart for the mean is typically based on the cumulative sum of the deviations of the individual observations (or the subgroup means) from the specified target mean. It seems natural to consider analogs of these charts using the nonparametric plotting statistics discussed earlier. These lead to nonparametric cumulative sum (NPCUSUM) charts.

Case K.

Charts for Location. Bakir and Reynolds [16] proposed a nonparametric CUSUM chart based on the SR statistic introduced earlier to monitor the median of a symmetric distribution with a known in-control value θ_0 . Recall that for the i th random sample, the plotting statistic in the Shewhart-type chart was $SR_i = \sum_{j=1}^n \text{sign}(X_{ij} - \theta_0) R_{ij}$, $i = 1, 2, \dots$. The Bakir–Reynolds grouped signed-rank (GSR) chart instead uses the cumulative sum of the statistic SR_i with a stopping rule. The GSR-CUSUM procedure is distribution free since the in-control distribution of SR_i does not depend on the underlying distribution for all continuous symmetric distributions.

The upper GSR chart uses the plotting statistic $SR_i^+ = \max(0, SR_{i-1}^+ + SR_i - k)$, with a starting value $SR_0^+ = 0$, and a signal is given for the first i when $SR_i^+ \geq h$. The lower GSR chart signals for the first i at which $SR_i^- \leq -h$, where $SR_i^- = \min(0, SR_{i-1}^- + SR_i + k)$ with a starting value $SR_0^- = 0$. The corresponding two-sided symmetric GSR chart signals for the first i at which either of the two inequalities is satisfied that is either $SR_i^+ \geq h$ or $SR_i^- \leq -h$. The statistics SR_i^+ and SR_i^- are reset to zero upon becoming negative and positive, respectively.

Bakir and Reynolds [16] derived the ARL of the chart using a **Markov chain** approach, where

the transition probabilities are calculated using the distribution of the SR statistic. In the in-control case and for small values of n , the distribution of the SR statistic has been tabulated and is available, for example, in Gibbons and Chakraborti [1]. The Markov chain approach is convenient for deriving the run length distribution of CUSUM charts and the associated properties. This approach appears particularly suitable in the nonparametric case since the plotting statistics (such as SR_i^+) are discrete.

One needs the reference value k and the decision value h in order to implement the CUSUM chart. Details regarding how to choose these constants are similar to that in the normal theory case. In fact, Bakir and Reynolds [16] recommended that the optimal k values they calculated for the normal distribution be used in practice unless very heavy tails of the process distribution are indicated. For example, for $n = 6$, one can take $k = 2$ in order to detect a shift of 0.2. Using this value of k , the value of h is chosen to achieve a desired in-control ARL value. They provided tables for the one-sided ARL_0 values, for various combinations of h, k , and n . For example, when n is 6, using $h = 10$ and $k = 11$, the upper GSR-CUSUM chart yields an in-control ARL of 301.01. Comparisons made on the basis of the one-sided ARL, with the Shewhart chart and the normal theory CUSUM chart for various positive shifts under the normal, uniform, double exponential and Cauchy distributions suggest that when observations are naturally collected in groups, the GSR chart is only slightly less efficient than the usual CUSUM chart based on the sample mean when the process is normally distributed, whereas for non-normal distributions the GSR chart can be considerably more efficient. A suitable subgroup size for this nonparametric procedure was suggested to be between $n = 5$ and 10, depending on the shift size and the desired in-control ARL. This recommendation is nearly the same as the subgroup size recommended for the normal theory-based procedures.

Following Bakir and Reynolds [16], Amin *et al.* [4] considered nonparametric CUSUM charts for the median of any continuous population by replacing the SR statistics with the sign statistics SN_i (recall that $SN_i = \sum_{j=1}^n \text{sign}(X_{ij} - \theta_0)$) in the definition of the CUSUM statistic. They also calculated the ARL of the chart using a Markov chain approach, where the transition probabilities are calculated *via* the distribution of the sign statistic, which is of course binomial. Optimal k and h are determined as in the case of the CUSUM of SR statistics by Bakir and Reynolds [16]; using k values for the normal distribution does not lead to large errors. Also, as in the case of the signed-rank CUSUM charts, it is seen that the sign CUSUM chart is generally more efficient than the Shewhart-type sign chart, with or without warning limits. However, more research is clearly necessary, including the full development of two-sided charts and guidelines for practical implementation of the nonparametric sign and the signed-rank CUSUM charts.

We illustrate the sign and signed-rank CUSUM charts using the same data used in Example 1. Recall that $n = 5$; Table 7 shows the upper and lower sign and signed-rank CUSUM statistics. For illustration, we take $k = 2$ for the sign CUSUM chart but for the signed-rank CUSUM chart we take $k = 3$, following Bakir and Reynolds [16], since n is odd. The decision value h for both charts was taken to be 8 for illustration. Figures 6 and 7 show a two-sided sign CUSUM chart and an upper signed-rank CUSUM chart, respectively.

The two-sided sign CUSUM chart signals at sample 13, indicating a most likely upward shift in the process median.

However, the upper signed-rank CUSUM chart signals earlier, at the seventh sample, again indicating a most likely upward shift in the process median. More work and guidance is necessary for the implementation of the sign and signed-rank CUSUM charts.

Table 7 One-sided sign (SN_i^+ and SN_i^-) and signed-rank (SR_i^+ and SR_i^-) statistics for nonparametric CUSUM charts

Sample number	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15
SN_i^+	0	0	0	1	0	1	2	0	1	3	2	5	8	11	13
SN_i^-	0	0	-2	0	0	0	0	0	0	0	0	0	0	0	0
SR_i^+	5	6	0	4	0	6	13	4	13	24	25	37	49	61	72
SR_i^-	0	0	-11	-1	-1	0	0	-3	0	0	0	0	0	0	0

Figure 6 Two-sided tabular sign CUSUM chart for the Montgomery [3]

Figure 7 Upper tabular signed-rank CUSUM chart for the Montgomery [3] piston-ring data

It is worth noting that while the CUSUM charts have been shown to be more efficient for small, sustained (persistent) shifts, this efficiency can be achieved only with a proper design of the chart, which means finding the optimum h and k values. This usually requires a specified shift and an ARL_0 .

This “tuning” of CUSUM charts is perhaps a bit more involved for a typical SPC practitioner.

Case U. Bakir [17] considered what are called *SR-like statistics* and used these to consider distribution-free charts. As earlier, in case U, the median of the

in-control distribution (assumed to be symmetric) is unknown and can be estimated by the median of a reference sample, say M . Then for the i th phase II sample, construct the SR-like plotting statistic $\varphi_i^* = \sum_{j=1}^n \text{sign}(Y_{ij} - M) R_{ij}^*$ where R_{ij}^* is the rank of $|Y_{ij} - M|$ among $|Y_{i1} - M|, \dots, |Y_{in} - M|$. This statistic is a direct analog of the plotting statistic SN_i used in case K. It is shown that this statistic is distribution-free and hence charts based on it are also distribution-free. Bakir [17] considered various charts including the Shewhart and the CUSUM based on φ^* . However, more work is necessary on the properties and implementation of these charts.

EWMA-Type Charts

Another popular class of control charts is the EWMA charts. The EWMA charts also take advantage of the sequentially (time ordered) accumulating nature of the data arising in a typical SPC environment and are known to be efficient in detecting smaller shifts but are easier to implement than the CUSUM charts. One can consider nonparametric EWMA-type charts using the plotting statistics or their suitable analogs, considered in cases K and U.

Case K.

Charts for Location. In the spirit of the grouped signed-rank cumulative sum (GSR-CUSUM) charts of Bakir and Reynolds [16], Amin and Searcy [18] considered a nonparametric EWMA chart (grouped signed-rank exponentially weighted **moving average** (GSR-EWMA)) of the SR statistics based on $Z_i = \lambda SR_i + (1 - \lambda)Z_{i-1}$, where λ ($0 < \lambda < 1$) is a smoothing constant. The starting value Z_0 is taken to be the process target value and the process is declared out-of-control at the first subgroup i when Z_i either falls above or below the control limits. Performance of the GSR-EWMA chart is found to be similar to that of the GSR-CUSUM charts. An advantage of the GSR-EWMA is its relative insensitivity to the choice of λ . In general, smaller (larger) λ values result in a faster detection of small (large) shifts. Enhancements such as addition of warning limits improve performance of the chart. **Autocorrelation** does not seem to affect the ARL as much it affects the ARL of an $\bar{X}$ -EWMA chart. Again, more work is necessary on the practical implementation of the charts as well as on adaptations in case U.

Other Charts

There has been other work on nonparametric control charts. Among these, for example, Albers and Kallenberg [19] studied conditions under which the nonparametric charts become viable alternatives to their parametric counterparts. They consider phase II charts for individual observations in case U based on empirical quartiles or order statistics. The basic problem is that for the very small FAR typically used in the industry, a very large reference sample size is usually necessary to set up the chart. They discuss various remedies for this problem.

Another area that has received some attention is control charts for variable sampling intervals (VSI). In a typical control charting environment, the time interval between two successive samples is fixed, and this called a *fixed sampling interval* (FSI) scheme. VSI schemes allow the user to vary the sampling interval between taking samples. This idea has intuitive appeal since when one or more charting statistics fall close to one of the control limits but not quite outside, it seems reasonable to sample more frequently, whereas when charting statistics plot closer to the centerline, no action is necessary and only a few samples might be sufficient. Amin and Widmaier [20] compared the Shewhart $\bar{X}$ charts with sign control charts, under the FSI and VSI schemes, on the basis of ARL for various shift sizes and several underlying distributions like the normal distribution and distributions that are heavy-tailed and/or asymmetric like the double exponential and the gamma. It is seen that the nonparametric VSI sign charts are more efficient than the corresponding FSI sign charts.

Nonparametric charts for individual observations are useful in practice; some work in this area has been done, see for example CVB.

Summary and Conclusions

Nonparametric control charts can be a useful tool for the quality practitioner in a variety of applications where not much is known or can be assumed about the process distribution (say regarding its shape or the variance). Although much has been accomplished in the last few years and a lot of work is currently underway, much more remains to be done. From a practical standpoint, the charting procedures must be made more accessible to the practitioner and to this end, the ease of implementation is vital.

Computer programs, add-ons to popular software packages such as Minitab and SAS, and/or websites would greatly help in this effort. In terms of research, more work needs to be done on charts for scale and on charts for simultaneous monitoring of location and scale parameters. Rank and rank-like statistics can be considered in a CUSUM and/or EWMA framework to design more powerful nonparametric charts. Moreover, the run length distributions of the various charts (both existing and new) need to be fully developed and examined, say in terms of various percentiles. Also, research is necessary on nonparametric control charts for phase I analysis as well as for discrete and categorical data.

GRAHAM

Variable Sampling Rate Control Charts

Introduction

Control charts are used to monitor a process to detect changes in the process and its output. The first control charts were developed by Walter A. Shewhart in the 1920s and were used in industrial applications. Control charts are now in widespread use throughout the world and have played a major role in improving quality and productivity in a wide range of applications. The application areas are no longer restricted to industrial and manufacturing settings, but include service industries, government, healthcare, and even law enforcement and athletics.

The traditional practice when using a control chart to monitor a process is to take samples of fixed size from the process using a fixed sampling interval between sampling points. For example, if the objective is to detect changes in the parameters of the distribution of a critical dimension of a component that is being manufactured, then this dimension might be measured for samples of $n = 4$ components taken using a sampling interval of $d = 4$ h. A control chart is operated by plotting a statistic, such as the sample mean or sample variance, after each sample is taken. If any plotted point falls outside of control limits that have been set up for the chart, then this is taken as strong evidence (a signal) that there has been a change in the process. The process is said to be in control if there has been no change in the process and out of control if there has been a change.

With the traditional Shewhart charts the statistic plotted at each sampling point is a function only of the sample at that sampling point. Other types of control charts, such as cumulative sum (CUSUM) charts (*see Cumulative Sum (CUSUM) Chart*) and exponentially weighted moving average (EWMA) charts (*see Exponentially Weighted Moving Average (EWMA) Control Chart*) are based on plotting statistics that are functions of current and past samples. CUSUM and EWMA charts are more effective than the traditional Shewhart charts for detecting small and moderate changes in the process parameters.

Standard control charts can be called *fixed sampling rate* (FSR) control charts because the sampling

rate is constant, but *variable sampling rate* (VSR) control charts vary the sampling rate as a function of the data obtained from the process being monitored. The basic idea behind VSR control charts is that the sampling rate should be increased when there is some indication of a problem with the process, and decreased when there is no indication of a problem with the process. If the indication of a problem with process is strong enough, then a VSR control chart signals in the same way as a standard FSR control chart. A review of VSR control charts, also called *adaptive sampling* control charts, was given by Tagaras [1].

Variable Sampling Interval (VSI) Control Charts

One class of VSR control charts consists of the *variable sampling interval* (VSI) control charts that vary the sampling interval as a function of the data from the process. With a VSI control chart a short sampling interval is used next when there is some indication of a problem with the process, and a longer sampling interval is used next when there is no indication of a problem with the process.

To develop an illustration of a VSI control chart, consider the standard FSR Shewhart $\bar{X}$ chart for monitoring the process mean, where the process observations are normal with mean μ and standard deviation σ . Let μ_0 and σ_0 be the in-control parameter values, which for simplicity, are assumed to be known or estimated with negligible error. Suppose that the standard FSR $\bar{X}$ chart is based on taking samples of size $n = 4$ from the process using a sampling interval of $d = 4$ h, and using 3σ control limits, $\mu_0 \pm 3\sigma_0/\sqrt{n}$. When the process is in control the probability of a signal (a false alarm) is 0.0027, and the *average number of samples to signal* (ANSS) is then $1/0.0027 = 370.4$. Samples are being taken every 4 h, so the in-control *average time to signal* (ATS) is then $(370.4)(4) = 1481.6$ h.

Consider now the application of a VSI $\bar{X}$ chart to this problem. Suppose that it is feasible to sample again as soon as 30 min after the previous sample and it is desirable to maintain the same average sampling rate (the rate of one observation per hour). Consider the VSI $\bar{X}$ chart that is based on two possible sampling intervals, $d_1 = 0.5$ h (30 min) and $d_2 = 6.0$ h, with an additional set of limits at $\mu_0 \pm$

2 Variable Sampling Rate Control Charts

$0.9052\sigma_0/\sqrt{n}$. The sampling rule is to use the long sampling interval d_2 next if the current value of $\bar{X}$ falls within the limits $\mu_0 \pm 0.9052\sigma_0/\sqrt{n}$, and use the short sampling interval d_1 next if the current value of $\bar{X}$ falls outside $\mu_0 \pm 0.9052\sigma_0/\sqrt{n}$ but within the control limits $\mu_0 \pm 3\sigma_0/\sqrt{n}$. A signal is given in the standard way if $\bar{X}$ falls outside $\mu_0 \pm 3\sigma_0/\sqrt{n}$. The value 0.9052 used in defining the inner limits was chosen so that, when the process is in control, the probability of being within these limits is 0.6364, conditional on no signal. This means that, when the process is in control, the probability of being outside $\mu_0 \pm 0.9052\sigma_0/\sqrt{n}$ but within $\mu_0 \pm 3\sigma_0/\sqrt{n}$ is 0.3636, conditional on no signal. Thus, conditional on no signal, the expected sampling interval is $(0.5)(0.3636) + (6.0)(0.6364) = 4.0$ h. Thus, this VSI $\bar{X}$ chart has been designed so that the in-control average sampling interval is the same as the standard FSR $\bar{X}$ chart.

Now consider the situation in which there is some change in the process and this change results in a one standard deviation shift in μ from μ_0 to $\mu_0 + \sigma_0$. The probability of $\bar{X}$ falling outside of $\mu_0 \pm 3\sigma_0/\sqrt{n}$ and resulting in a signal is now 0.1587. The ANSS of both the FSR and VSI $\bar{X}$ charts is thus $1/0.1587 = 6.3030$. Now if $\mu = \mu_0 + \sigma_0$, the probability that the VSI chart uses the short sampling interval has increased to 0.8396, and the probability of using the long sampling interval has decreased to 0.1604. Thus, the average sampling interval of the VSI chart, conditional on no signal, will be $(0.5)(0.8396) + (6.0)(0.1604) = 1.3823$ h. Then, the out-of-control ATS for detecting this shift will be $(6.3030)(1.3823) = 8.71$ h. Note that the standard FSR $\bar{X}$ chart always uses a sampling interval of 4.0 h, so the out-of-control ATS of this chart is $(6.3030)(4.0) = 25.21$ h. Therefore, the VSI $\bar{X}$ chart will detect this shift much faster, on average, than the standard FSR $\bar{X}$ chart, because the shift in the mean has caused the VSI chart to sample at a higher rate.

The first VSI charts to be developed were Shewhart-type charts (see, for example, Reynolds *et al.* [2], Cui and Reynolds [3], and Runger and Pignatiello [4]). Since the development of the VSI Shewhart charts, the VSI idea has been extended to other types of charts. Reynolds *et al.* [5] developed a VSI CUSUM chart, and Saccucci *et al.* [6] developed a VSI EWMA chart.

Most work on VSI charts has concentrated on the problem of monitoring μ , but in practice it is usually

important to monitor both μ and σ . Shamma and Amin [7] investigated the performance of a single VSI EWMA chart that can be used to simultaneously monitor μ and σ . Reynolds and Stoumbos [8] and Stoumbos and Reynolds [9] investigated combinations of VSI Shewhart and EWMA charts for the problem of simultaneously monitoring μ and σ . Reynolds and Cho [39] developed multivariate (see **Multivariate Control Charts Overview**) VSI charts for monitoring the process mean and variability.

In the illustration of the VSI $\bar{X}$ chart discussed above, only two possible sampling intervals, $d_1 = 0.5$ h and $d_2 = 6.0$ h, were allowed. It might seem that it would be better to allow more than two possible sampling intervals, but computational and theoretical results have shown that allowing only two possible intervals is optimal or near optimal. See Reynolds and Arnold [11], Reynolds [12, 13], and Stoumbos *et al.* [14].

VSI Control Charts with Sampling at Fixed Times

The VSI $\bar{X}$ chart discussed as an example above used two possible sampling intervals, 0.5 and 6.0 h, and was compared to a standard FSR $\bar{X}$ chart that sampled every 4.0 h. In some applications, it may be desirable to sample at certain specified fixed times. For example, if process personnel work 8-h shifts, then the standard FSR $\bar{X}$ chart is based on two samples every shift. However, the sampling intervals of the VSI chart are either 0.5 or 6.0 h, depending on the data from the process, so the sampling points for the VSI chart will be unpredictable.

If it is desirable for sampling to be more predictable, the VSI chart sampling decision rules could be modified to specify that samples always be taken at specified fixed times. For example, it could be specified that samples always be taken every 4 h, with additional samples taken within each 4-h interval whenever necessary. This would result in the VSI chart sampling at a higher average rate than the FSR chart. Alternately, it could be specified that the VSI chart samples once during each 8-h work shift, with additional samples taken within the 8-h period only when necessary. In this case, the VSI chart would be sampling less often, on average, than the FSR chart.

See Reynolds [15, 16], Baxley [17], and Stoumbos and Reynolds [18] for discussion of this modification of VSI charts.

Variable Sample Size (VSS) Control Charts

Another class of VSR control charts consists of the *variable sample size* (VSS) control charts that vary the sample size as a function of the data from the process. With a VSS control chart a large sample size is used next when there is some indication of a problem with the process, and a small sample size is used next when there is no indication of a problem with the process.

To develop an illustration of a VSS control chart, consider the situation discussed previously in which the standard FSR Shewhart $\bar{X}$ chart is based on taking samples of size $n = 4$, with a sampling interval of $d = 4$ h, and control limits $\mu_0 \pm 3\sigma_0/\sqrt{n}$.

Consider the applications of a VSS $\bar{X}$ chart to this problem. Suppose that it is feasible to take a sample of eight observations whenever it appears to be necessary and it is desirable to maintain an average sampling rate of one observation per hour. Consider the VSS $\bar{X}$ chart based on two possible sample sizes, $n_1 = 2$ and $n_2 = 8$, and an additional set of limits at $\mu_0 \pm 0.9638\sigma_0/\sqrt{n}$. The sampling rule is to use the small sample size n_1 next if the current value of $\bar{X}$ falls within the limits $\mu_0 \pm 0.9638\sigma_0/\sqrt{n}$, and use the large sample size n_2 next if the current value of $\bar{X}$ falls outside $\mu_0 \pm 0.9638\sigma_0/\sqrt{n}$ but within the control limits $\mu_0 \pm 3\sigma_0/\sqrt{n}$. A signal is given in the standard way if $\bar{X}$ falls outside $\mu_0 \pm 3\sigma_0/\sqrt{n}$. The value 0.9638 used in defining the inner limits was chosen so that, when the process is in control, the probability of being within these limits is 0.6667, conditional on no signal. This means that, when the process is in control, the probability of being outside $\mu_0 \pm 0.9638\sigma_0/\sqrt{n}$ but within $\mu_0 \pm 3\sigma_0/\sqrt{n}$ is 0.3333, conditional on no signal. Thus, conditional on no signal, the expected sample size is $(2)(0.3333) + (8)(0.6667) = 4$. Thus, this VSS $\bar{X}$ chart has been designed so that the in-control average sample size is the same as the sample size for the standard FSR $\bar{X}$ chart. Note that both sets of limits involve $\sqrt{n}$, and the value of n to be used in these limits depends on the sample size being used in the current sample.

When there is a shift in the process mean, the probability of using the large sample size n_2 will increase, while the probability of using the small sample size n_1 will decrease. If the large sample size is used more frequently, then the expected number of samples required for detection will decrease, leading to faster detection of this shift.

The first VSS charts to be developed were Shewhart-type charts (see, for example, Prabhu *et al.* [19] and Costa [20]). Since the development of the VSS Shewhart charts, the VSS idea has been extended to other types of charts. Annadi *et al.* [21] developed a VSS CUSUM control chart.

In the illustration of the VSS $\bar{X}$ discussed above, only two possible sample intervals, $n_1 = 2$ and $n_2 = 8$, were allowed. There are no theoretical results that give the optimal number of possible sample sizes, but using only two possible sample sizes seems to give good performance and provides relatively simple sampling rules for the VSS chart.

VSI–VSS Control Charts

The VSI and VSS approaches to varying the sampling rate can be used simultaneously. The basic idea would be to use a short sampling interval and large sample size next if there is some indication of a problem with the process, and a long sampling interval and small sample size next if there is no indication of a problem. Thus, in addition to the control limits, two other sets of limits could be added to the chart. One set of limits would be used to determine the next sampling interval, and the other to determine the next sample size. The control limits would be used as usual to determine when to signal.

For VSI–VSS Shewhart charts see, for example, Prabhu *et al.* [22], Costa [23], and Park and Reynolds [24]. Arnold and Reynolds [25] developed VSI–VSS CUSUM charts, and Reynolds and Arnold [26] developed VSI–VSS EWMA charts. Aparisi and Haro [27] investigated multivariate VSI–VSS Shewhart-type charts.

Control Charts Based on Sequential Sampling

Another approach to implementing the VSR concept is related to the VSS approach, but the sample size is changed in a different way. With standard VSS

control charts, as usually defined, the sample size for the current sample is determined by past process data, before sampling starts for the current sample. Another approach, called *sequential sampling* allows the sample size at a sampling point to be determined by the data at that sampling point (along with the data at previous sampling points). With sequential sampling, at each sampling point observations are taken in groups of one or more. After each group is taken at a sampling point, a decision is made to either take another group at this sampling point, wait until the next sampling point to sample again, or signal at the current sampling point. Sequential sampling is appropriate for situations in which sampling must be done at equally spaced sampling points, and it is feasible to take samples consisting of multiple groups of observations at a sampling point whenever necessary.

The first work on sequential sampling control charts was for Shewhart charts with a maximum of two groups allowed at each sampling point (see Croasdale [28] and Daudin [29]). Better performance can be achieved if multiple groups are allowed at a sampling point. An extension is the case in which observations are taken individually, with no limit on the number of observations at a sampling point. When the objective is to detect a parameter shift in one direction, a very efficient sequential sampling scheme can be obtained by applying a sequential probability ratio test (SPRT) at each sampling point (see Stoumbos and Reynolds [18, 30, 31] and Reynolds and Stoumbos [32]).

Reynolds and Kim [33] developed multivariate sequential sampling schemes for monitoring the process mean, and Reynolds and Kim [34] developed multivariate sequential sampling schemes for simultaneously monitoring the process mean and variability.

In general, sequential sampling schemes can be comparable in performance to the best VSI or VSS schemes, and all of these schemes will provide very substantial improvements in performance compared to traditional FSR control charts.

Conclusions and Discussion

Using the VSR feature in process monitoring can give very substantial improvements in the ability to detect process changes. A number of approaches to varying the sampling rate as a function of the

process data have been discussed here. The approach that gives the best overall performance depends on which type of control chart is being used and on the constraints placed on sampling. Sampling constraints include the smallest feasible sampling interval, the largest feasible sample size, and requirements that sampling be done at specified fixed sampling points in time.

Earlier in this article the application of the VSI and VSS features was illustrated in the context of the simple Shewhart $\bar{X}$ chart for monitoring μ . In most applications, it will also be important to simultaneously monitor both μ and σ . Combinations of two Shewhart charts, such as the $\bar{X}$ chart and the R chart, have traditionally been used to monitor μ and σ . Although Shewhart charts have the advantage of simplicity, recent research (see, for example, Reynolds and Stoumbos [35–37] and Reynolds and Cho [10]) has shown that combinations of EWMA or CUSUM charts have better overall statistical performance than Shewhart chart combinations for the problem of simultaneously monitoring μ and σ . Thus, we recommend that combinations of EWMA or CUSUM charts be used in applications instead of Shewhart chart combinations.

Recent research (see, for example, Hawkins and Olwell [38], Reynolds and Stoumbos [35–37] and Reynolds and Cho [10]) has also shown that with EWMA or CUSUM charts the best overall statistical performance is achieved by taking small frequent samples instead of taking larger samples less frequently. For example, if there is a choice between taking samples of $n = 4$ every $d = 4$ h or samples of $n = 1$ every $d = 1$ h, then it is better overall to take samples of $n = 1$ every hour. However, samples of size $n = 4$ might be reasonable when there is a significant cost-saving from sampling in groups of $n = 4$ instead of sampling individual observations. Taking samples of $n = 4$ would also be reasonable if Shewhart charts are being used, because the best value of n for Shewhart charts is not the same as the best value of n for EWMA or CUSUM charts.

The fact that $n = 1$ gives the best overall performance for EWMA or CUSUM charts suggests that the best approach to applying the VSR concept is through the VSI feature with $n = 1$, because using the VSS feature assumes that samples of $n > 1$ will sometimes be taken. However, there are a number of situations in which it may be appropriate to use the VSS or sequential sampling features. For example,

suppose that items are produced in batches, a batch takes 4 h to process, and the current practice is to take samples of $n = 4$ from each batch. In this situation, the VSI approach does not seem to be applicable, so a good option would be to use the VSS or sequential sampling features, where the sample size within a batch can vary depending on the process data.

The use of the VSR feature in applications requires that procedures for designing a VSR chart be available. Design procedures can include software or tables that give appropriate VSR chart parameters, such as the limits that determine when to use each sampling interval or sample size. Design procedures are available in many of the references previously cited here, but these design procedures tend to be for relatively simple cases involving the monitoring of only one parameter, such as μ . However, Reynolds and Stoumbos [8] discuss the design of combinations of VSI EWMA charts for the simultaneous monitoring of μ and σ when $n = 1$. More work is needed to develop easy-to-use design procedures for other combinations of VSR control charts.

Neural Networks: Construction and Evaluation

Introduction

Neural network (NN) stems from the thought of trying to mimic the ability of the human brain in both structure and function. The human brain contains many billions of nerve cells, or neurons. Each neuron is a cell, which connects to other neurons through synapses. Each neuron also uses biochemical reactions to receive, process, and transmit information. Following this idea, NNs have been designed to achieve human brain-like performance and have been applied in many fields of study including statistics.

A NN model (*see Neural Networks in Statistical Process Control*) is usually demonstrated as layers of functional units, called nodes or neurons or perceptrons. There are at least two layers, input and output. However, a NN normally has an additional layer referred to as a “*hidden layer*”. Nodes of the NN are connected by weights. The nodes and weights of the NN are comparable to neurons and synapses, respectively. Hence, the NN model solves a problem by finding optimal weights. Typically, NNs are utilized in three problem areas: (a) classification and diagnosis, (b) function approximation and prediction, and (c) optimization.

The type of NN is defined the NN architecture or topology. Lippmann [1] provides an introduction to six important NNs that can be used for pattern classification: (a) Hopfield net, (b) Hamming net, (c) Carpenter–Grosberg classifier, (d) perceptron, (e) multi-layer perceptron (MLP), and (f) Kohonen self-organizing feature maps. Existing NN architectures currently used are: MLP, radial basis function (RBF), learning vector quantization (LVQ), adaptive resonance theory (ART), auto-associative NNs, and Kohonen self-organizing maps (SOM).

To construct a NN model, there are five important factors for consideration.

1. NN architecture

Different NN architectures have different rules for solving modeling problems. Learning or training is the term used to explain the process of finding

the weights. There are two types of NN training. Supervised learning is known as learning with a teacher. It happens when there is a known target value associated with the input nodes. One of the most popular algorithms used in supervised learning is back-propagation. Unsupervised learning is known as learning without a teacher. It occurs when data lack target output values relating to the pattern of input nodes. The algorithms of unsupervised learning can be found in Lippmann [1].

2. Number of hidden layers

Since the nodes in the input layer only pass data to other layers, computation occurs in both hidden layers and the output layer. Adding additional hidden layers to solve a problem may provide a better result than use of only two-layer, input and output, networks. However, there is no rule of thumb for the suitable number of hidden layers. The more the hidden layers, the larger the NN size, which leads to overfitting (overtraining) problems. On the other hand, too few hidden layers cause underfitting (undertraining) problems.

3. Number of nodes in each layer

Generally, input layer nodes are directly related to the number of observations needed to represent each set of input variables. No guidelines exist for the number of hidden layer nodes as with the number of hidden layers. Overfitting problems occur when there are too many hidden nodes, and underfitting problems when there are too few hidden nodes. Output layer nodes correspond to the anticipated number of distinct patterns or classifications that are to be decided by the network.

4. Type of connection

In a full-connection network every single node in a layer connects to every node in the next layer. Otherwise, it is a partial-connection network. In addition, there is a feed-forward network in which nodes in each layer can only be connected to other nodes in the next layer, while in the recurrent network nodes in each layer can be connected to the nodes in the previous layer, next layer and even nodes in the same layer.

5. Activation function or transfer function

This function occurs at every computational node, both hidden and output. It can be either linear or non-linear, symmetrical or nonsymmetrical. Two common functions widely used are the sigmoid function (logistic function) and hyperbolic tangent function (*see Neural Networks in Statistical Process Control*).

An Example: NNs for Multivariate Quality Control

Traditional **multivariate control charts**, such as the chi-square (*see Hotelling's T^2 Chart*) and the multivariate exponentially weighted moving average (MEWMA) charts (*see Multivariate Exponentially Weighted Moving Average (MEWMA) Control Chart*), are commonly used for monitoring a process and detecting process shifts when there are several correlated quality characteristics. These two traditional techniques make three important assumptions:

1. the data follow a multivariate **normal distribution**,
2. the **covariance** matrix is constant over time, and
3. the observations are independent over time.

The performance of both charts is seriously affected if any of these assumptions is not met. The NN then becomes an alternative for consideration because it does not require such strict assumptions. The NN approach finds the relationships between input variables and output variables from existing data. Therefore, an appropriately designed NN may be easier for practitioners to use and more robust to traditional assumptions, while providing equal or improved performance relative to traditional multivariate statistical process control (SPC) methods.

The bivariate case is illustrated using simulated data written by the interactive matrix language procedure (Proc IML) of Statistical Analysis System (SAS) for generating multivariate observations and assessing the performance of the three different methods based on the average run length (ARLs). For each method, ARLs were calculated for both the in-control and out-of-control state, over the total number of observations, to compare the performance of all three methods. As described briefly in the previous section, there are many NN architectures that may be applied to classification problems, which are focused on a change in structure for mean shifts, assuming constant variance. The MLP is one feasible NN architecture. Advantages of the MLP are its simplicity and flexibility.

Construction of a Neural Network for SPC

1. NN architecture

The feed-forward MLP with back-propagation is a feasible and suitable NN because of its simplicity.

2. Type of connection

A full connection is used following the recommendation of Pugh [2] and Chang and Aw [3] as this approach speeds network convergence.

3. Number of hidden layers

Only one hidden layer is used following the result of Pugh [2, 4] as no significant performance difference is reported for the MLP with one-hidden layer or two-hidden layers.

4. Number of nodes

(a) Input layer nodes

There are two issues that affect the appropriate number of nodes for a NN.

First, if the problem does not address pattern recognition, the input layer contains only the current observation, regardless of preceding and succeeding data. Hence, each input node might be the vector of current quality characteristic mean of each observation sized n . There are then two input nodes. Each of them represents the sample mean of each i th observation for the first and second quality variable, respectively, as the vector of $(\bar{X}_1, \bar{X}_2)$, where $\bar{X}_j = \frac{\sum_{k=1}^n x_{ijk}}{n}$. Summarizing a multivariate sample by using the sample mean vector NN inputs may be considered as pre-processing of the data. Note that this procedure is based on the assumption of a constant variance matrix of two correlated variables. One should also note that the training phase for NN modeling with SPC requires data from both in-control and out-of-control process states. This is quite different from the traditional methods which require phase I data to be from an in-control process.

The other situation is that when pattern recognition is addressed, preceding data are supplied to the NN through the input nodes, in addition to current data. Three consecutive observations then are considered at time periods t , $t-1$, and $t-2$, respectively. In each time period, there is the vector of sample means for the first and second quality variable. Hence, there are six input nodes expressed by $(\bar{X}_{(t,1)}, \bar{X}_{(t,2)}, \bar{X}_{(t-1,1)}, \bar{X}_{(t-1,2)}, \bar{X}_{(t-2,1)}, \bar{X}_{(t-2,2)})$, where $\bar{X}_{(i,j)}$ is the sample mean for the quality characteristic j , $j = 1, 2$, at time period i for $i = t, t-1, t-2$.

(b) Hidden layer nodes

As Guo and Dooley [5] reported, there is no standard rule for deciding the optimum number of hidden layer nodes. The primary concern is

the overtraining or undertraining problem. Thus the performance of NN is illustrated with three and five hidden nodes.

(c) Output layer nodes

Only one output node is required since we are only interested in a change in structure from an in-control state to an out-of-control state. One might consider multiple outputs to signal various changes such as changes in the variance–covariance structures or mean shifts in specific directions.

Four NN architectures are illustrated. They are graphically displayed in Figures 1–4.

5. Cutoff point estimation

At the final step of NN process monitoring, the NN output must be checked against its appropriate cutoff point (control limit) to determine whether the process is in control. Based on the idea of a false alarm rate, α , the cutoff point is determined from the **quantiles** of the predicted values for in-control data. For example, if the false alarm rate, α , equals 0.005 and there are 10 000 and 15 000 observations of in-control data, so the cutoff point is at the 0.005 quantile of the network output distribution. Yi *et al.* [6] used this method to compare **ARL** performances between MLP NNs and $\bar{X}$ control charts for investigating nonnormally distributed quality characteristics.

Since the distribution of the cutoff point is also not known, using a smoothed estimate rather than the sample quantile may be better. The smoothed estimate of the 99.995th percentile, known as the

Figure 1 MLP with two input nodes, and three hidden nodes in a hidden layer (NN2(3))

Figure 2 MLP with two input nodes, and five hidden nodes in a hidden layer (NN2(5))

Figure 3 MLP with six input nodes, and three hidden nodes in a hidden layer (NN6(3))

Harrell-Davis [7] estimator, might be provided a starting point for determining more accurate cutoff points through simulation.

Performance of the Illustrated NN Systems

All competing monitoring schemes are designed to provide equal in-control ARLs of 200. The out-of-control ARL of each method is used to compare

4 Neural Networks: Construction and Evaluation

Figure 4 MLP with six input nodes, and five hidden nodes in a hidden layer (NN6(5))

performances under two different shift sizes, small and large shifts, as measured by the noncentrality parameter term, δ , as

$$\delta^2(\mu) = (\mu - \mu_0)' \sum^{-1} (\mu - \mu_0)$$

where μ_0 is the in-control mean vector and μ is the current mean vector. A large value of δ indicates that there are big shifts in the mean. If the value of $\delta = 0$ ($\mu = \mu_0$), the process is in control. In addition to the size of the shift, the performances of the NN methods are evaluated for one-variable shifts along the x-axis and two-variable shifts along the major and minor axes of the bivariate distribution. A major axis shift

is defined in the eigenvector direction associated with the largest eigenvalue of the inverse of covariance (correlation) matrix and a minor axis shift is in the eigenvector direction associated with the smallest eigenvalue of the inverse of covariance (correlation) matrix. NNs are trained using two different sizes of data sets, small and large sizes, consisting of 20 000 and 30 000 observations. Monitoring schemes exhibiting best ARL performances across the various illustrated conditions are provided in Figures 5 and 6.

As for training NN with smaller training set, the NN6(3) provides the best performance at the large shift. For small shifts, the MEWMA method provides the best performance if the variables are not highly correlated. However, if the variables are highly correlated, the NN6(3) provides the best performance. Similar results are obtained for training NN with larger training sets.

Figure 5 A graphical display of optimal methods for a one-variable shift

Figure 6 A graphical display of optimal methods for two-variable shifts

For two-variable shifts, four factors, covariance (A), shift size (B), training size (E), and direction of shift (F), each at two levels, are of interest. The graphical display of the optimal method at each condition is shown in Figure 6.

The interested reader can find additional information regarding the use of NN models in multivariate quality in Saithanu [8].

Strengths

The practitioner will find many advantages to using NN-based monitoring schemes. These advantages include good performance and flexibility. The flexibility of this method refers not only to relaxation of distributional assumptions associated with traditional methods, but also includes flexibility in applications. Univariate, multivariate, and regression-based applications (see **Regression Control Charts**), as well as special purpose systems, are legitimate candidates for NN modeling.

Weaknesses

NNs come with some disadvantages or weaknesses. Some of these disadvantages are associated with the lack of experience most practitioners have with NN models. The selection of an appropriate architecture as well as training issues may require steep learning curves for the inexperienced. There is also the matter of model interpretation that is problematic for NN models. Finally, NN models and their development are computational intensive. These computational requirements come in several forms. Two of the most immediate issues are the need for specialized software and the need for large training datasets.

Conclusions

The NN is a very flexible tool that provides competitive performances relative to more traditional process monitoring schemes. The development of these monitoring systems has requirements that are somewhat unique to this method. The need for both in-control and out-of-control data for the training phase, large training datasets and specialized software have been mentioned in this article. The software required to design and develop NN models continues to become more mainstream and available to practitioners. In complex high volume production environments, where large data sets are common, the practitioner may be well served by NN-based monitoring systems.

KIDAKAN SAITHANU

Control Charts for Short Production Runs

Introduction

Shewhart **control charts** are used to monitor both products and processes to determine if and when action should be taken to adjust a process because of changes in centering and/or spread of the quality characteristic being measured. In Shewhart control charting, m subgroups of size n consisting of measurements of a quality characteristic of a part or process are collected. The mean ($\bar{X}$) in combination with the range (R), variance (v), or standard deviation (s) is calculated for each subgroup. When the subgroup size is 1, individual values (denoted by X) are used in combination with moving ranges (denoted by MR) of size 2. The mean of the subgroup means ($\bar{\bar{X}}$) and subgroup ranges ($\bar{R}$), variances ($\bar{v}$), or standard deviations ($\bar{s}$) are calculated and used to determine estimates of the process mean and standard deviation, respectively. When the subgroup size is 1, the mean of the individual values ($\bar{X}$) and moving ranges ($\bar{MR}$) are used for this purpose. These parameter estimates are then used to construct control limits using conventional control chart constants for monitoring the performance of the process. These conventional control chart constants assume that an infinite number of subgroups are available to estimate the process mean and standard deviation.

Hillier [1] presented three situations in which this assumption is invalid. The first is in the initiation of a new process. The second is during the start-up of a process just brought into statistical control again. The third is for a process whose total output is not large enough to use conventional control chart constants. Each of these is an example of a short-run situation. In a short-run situation, little or no historical information is available about a process in order to estimate the process mean and standard deviation to begin control charting. Consequently, the initial data obtained from the early run of the process must be used for this purpose.

In recent years, manufacturing companies have increasingly faced each of these short-run situations. One reason is the widespread application of the just-in-time (JIT) philosophy, which has caused much

shorter continuous runs of products. Other reasons are frequently changing product lines and product characteristics caused by shorter-lived products, fast-paced product innovation, and changing consumer demand. Fortunately, flexible manufacturing technology has provided companies with the ability to alter their processes in order to face these challenges. However, traditional statistical process control (SPC) methodologies do not provide companies with the ability to reliably monitor quality in each of the previously mentioned short-run situations. A common rule of thumb, which has been widely accepted despite evidence that it may be incorrect, states that 20–30 subgroups of size 4 or 5 are necessary before parameter estimates may be obtained to construct control limits using conventional control chart constants. This is a difficult if not an impossible rule to satisfy in a short-run situation. As a result, SPC methodologies have been developed for monitoring quality in each of the previously mentioned short-run situations. Though several of these methodologies are discussed here, the particular focus of this discussion is the two-stage short-run control charting methodology.

Pooling Data

The prevalent methodologies focus on pooling data from different parts onto a single control chart combination (i.e., onto $(\bar{X}, R)$, $(\bar{X}, v)$, $(\bar{X}, \sqrt{v})$, $(\bar{X}, s)$, and (X, MR) control charts) in order to have enough data to satisfy the rule. The difference between $(\bar{X}, \sqrt{v})$ and $(\bar{X}, s)$ control charts is that the former are constructed using the statistic $\sqrt{\bar{v}}$ and the latter are constructed using the statistic $\bar{s}$. Pooling data is the procedure of taking measurements of quality characteristics from different parts, performing a transformation on the measurements, and plotting the transformed measurements from the different parts on the same control chart. Typically, all of the part numbers on the same control chart are produced by one machine or process. Hence, control charting using pooled data is often termed a *process-focused approach* rather than a *product-focused approach* to control charting. Elam [2] provided references for pooled data control charts. For example, see [3, 4].

Pooling data is advantageous because it reduces the number of control charts in use, which greatly simplifies control chart management programs. Also,

2 Control Charts for Short Production Runs

in most cases, control charting can begin almost immediately after the start-up of a process because control limits are known and constant. However, pooling data has several problems. In a true short-run situation, one will often find it difficult to even proceed to pool data. The reason is that, to construct control limits from pooled data, many part types or operations with similar characteristics must be produced or performed, respectively, by the same process.

Another problem is process parameters for each part number are estimated using target or nominal values, tolerances, specification limits, initial subgroups drawn from the process, or historical data. Using target or nominal values is equivalent to using specification limits instead of statistical control limits on control charts, which is a serious mistake. The same can be said for tolerances and specification limits. The reason is that the process target (what you want), the process aim (what you set), and the process average (what you get) are never the same. The magnitude of the differences depends on how well the process is performing. The result is a control chart that, in general, will be useless in delineating special cause variation from common cause variation.

Using initial subgroups drawn from the process to obtain parameter estimates for part numbers begs the original short-run problem that motivates the use of pooled data. If one has enough data (as defined by the common rule of thumb) from a process for a single part to estimate its process parameters, then pooling data is not necessary in the first place. When one has historical data to estimate process parameters for part numbers, then by definition one is not in a short-run situation. Consequently, pooling data is not even necessary, other than to reduce the number of control charts in use.

Finally, an original motivation for pooling data was to satisfy the common rule of thumb. However, satisfying the rule does not guarantee control limits that result in the desired false alarm rate and have a high probability of detecting a special cause signal.

Greater Sensitivity

A second approach to control charting in a short-run situation is using control charts with greater sensitivity (i.e., more statistical **power**) than Shewhart

control charts. In a short-run situation, the total output of the process is not large. Consequently, the quick detection of special cause signals takes on added importance. It is well known that cumulative sum (**CUSUM**) and **exponentially weighted moving average** (**EWMA**) control schemes are more sensitive to detecting small process shifts than Shewhart control charts. Also, economically designed control charts have greater sensitivity. Consequently, these have been adapted for use in short-run situations. Elam [2] provided references for greater sensitivity control charts. For example, Hawkins [5] presents variations of CUSUM and EWMA control schemes to be used in short-run situations, Doganaksoy and Vandeven [6] combine CUSUM and EWMA control schemes with other control chart methodologies for use in short-run situations, and Del Castillo and Montgomery [7] present economically designed control charts for short-run situations.

An advantage of this approach is that it allows for the quick detection of special cause signals. A disadvantage is that initial estimates of the process parameters must be close to their true values in order for the control charts to perform well. Also, the methodologies that comprise this approach are difficult to implement.

Process Inputs

A third approach to control charting in a short-run situation is to monitor and control process inputs rather than process outputs. The assumption upon which this approach is based is that, by correctly selecting and monitoring critical input variables, one can control the output of the process. Elam [2] provided references for process input control charts.

An advantage of this approach is that, since large amounts of process input data may be available even in a short-run situation, Shewhart control charting may be used. A problem with this approach is that critical input parameters for a new part to be produced in a short run may not match all of the critical input parameters for which large amounts of data are available. Also, this approach assumes that the process input nominal values are the same for all products fabricated on that process. If nominal values are different, a transformation of the process input data may be required.

Control Charts with Modified Limits

A fourth approach to control charting in a short-run situation is using control charts with modified limits. In a true short-run situation, the process mean and standard deviation are unknown and must be estimated from a small number of subgroups with only a few samples each drawn from the start-up of a process. When these estimates are used with conventional control chart constants to construct control limits for $(\bar{X}, R)$, $(\bar{X}, v)$, $(\bar{X}, \sqrt{v})$, $(\bar{X}, s)$, and $(\bar{X}, MR)$ control charts, the false alarm probability becomes distorted. Consequently, modified control chart factors need to be used to achieve the desired false alarm probability.

Elam [2] provided references up to 2001 for control charting techniques that fall under this approach. One of these techniques is the Q chart methodology (see [8]). It is advantageous in that, not only does it allow for the pooling of data from different parts, but different statistics may be plotted on the same Q chart. Also, control charting can begin almost immediately after the start-up of a process because control limits are known and constant. Disadvantages of Q charts are their inability to detect a process that starts out of control and their general lack of sensitivity in detecting process changes. Also, process standard deviation estimates used to calculate Q statistics to be plotted on Q charts are unreliable.

Two-Stage Short-Run Control Charts

Hillier [1] developed a two-stage short-run theory of control charting. Though this was one of the first short-run control charting methodologies, focus shifted to the previously discussed approaches in the 1980s and 1990s. The two-stage procedure is used to determine both the initial state of the process and the control limits for testing the future performance of the process. In the first stage, the initial subgroups drawn from the process are used to determine the control limits. The initial subgroups are plotted against the control limits to retrospectively test if the process was in-control while the initial subgroups were being drawn. Any out-of-control initial subgroups are deleted using a delete and revise (D&R) procedure. Once control is established, the procedure moves to the second stage, where the initial subgroups that were not deleted in the first stage are used to determine the control limits for testing if the process

remains in-control while future subgroups are drawn. Each stage uses a different set of control chart factors called *first-stage short-run control chart factors* and *second-stage short-run control chart factors*.

Hillier [1] applied his two-stage short-run control charting methodology to $(\bar{X}, R)$ control charts. The methodology allows for the specification of the desired false alarm probability. Hillier [1] included the methodology for second-stage short-run control charting for $\bar{X}$ charts and R charts presented by Hillier [9] and Hillier [10], respectively. Hillier [9] showed that the probability of a false alarm is exceedingly high when estimates of the process mean and standard deviation based on a small number of subgroups are used together with conventional control chart constants to construct $\bar{X}$ charts for future testing (stage two). To resolve this issue, Hillier [9] derived an equation for A_2^* , the second-stage short-run control chart factor for the $\bar{X}$ chart. Using this factor, which depends on m (the number of subgroups) as well as the subgroup size n , instead of the conventional control chart constant A_2 results in control limits that give the desired false alarm probability. The value A_2^* is related to A_2 in that, as $m \rightarrow \infty$, $A_2^* \rightarrow A_2$.

Hillier [10] showed that the probability of a false alarm is exceedingly high when estimates of the process standard deviation based on a small number of subgroups are used together with conventional control chart constants to construct R charts for future testing (stage two). To resolve this issue, he [10] derived equations for D_4^* and D_3^* , the second-stage short-run upper and lower control chart factors, respectively, for the R chart. Using these factors, which depend on m as well as n , instead of the corresponding α -based (i.e., probability based) conventional upper and lower control chart constants D_4 and D_3 , respectively, result in control limits that give the desired false alarm probability. The value D_4^* is related to D_4 in that, as $m \rightarrow \infty$, $D_4^* \rightarrow D_4$. Similarly, the value D_3^* is related to D_3 in that, as $m \rightarrow \infty$, $D_3^* \rightarrow D_3$.

Hillier [1] incorporated the two-stage procedure with his results in [9, 10] and derived equations to calculate first- and second-stage short-run control chart factors, for $(\bar{X}, R)$ charts. Using these factors, when process parameter estimates come from a small number of subgroups, results in control chart limits that reliably indicate when a process has gone out of control. The first-stage short-run control chart factor

4 Control Charts for Short Production Runs

for the $\bar{X}$ chart is denoted by A_2^{**} . It depends on m as well as n . The value A_2^{**} is related to A_2 in that, as $m \rightarrow \infty$, $A_2^{**} \rightarrow A_2$. The first-stage short-run upper and lower control chart factors for the R chart are denoted by D_4^{**} and D_3^{**} , respectively. Each of these factors depends on m as well as n . As $m \rightarrow \infty$, $D_4^{**} \rightarrow D_4$ and $D_3^{**} \rightarrow D_3$.

Discussion and computer software for designing two-stage short-run control charts may be found in [11–17] for $(\bar{X}, R)$, $(\bar{X}, v)$ and $(\bar{X}, \sqrt{v})$, $(\bar{X}, s)$, and (X, MR) applications, respectively. The following is an example for two-stage short-run $(\bar{X}, R)$ control charts. Table 1 has the data. For $m = 5$ and $n = 4$, the following first-stage short-run control chart factors are obtained from Table A4 in [11]: $A_2^{**} = 0.77660$, $D_4^{**} = 2.11840$, and $D_3^{**} = 0.11338$. First-stage short-run control limits are calculated as follows: $UCL(R) = D_4^{**} \times \bar{R} = 2.11840 \times 0.216 = 0.45757$, $LCL(R) = D_3^{**} \times \bar{R} = 0.11338 \times 0.216 = 0.02449$, $UCL(\bar{X}) = \bar{\bar{X}} + A_2^{**} \times \bar{R} = 1.286 + 0.77660 \times 0.216 = 1.45375$, and $LCL(\bar{X}) = \bar{\bar{X}} - A_2^{**} \times \bar{R} = 1.286 - 0.77660 \times 0.216 = 1.11825$. R for subgroup five ($R = 0.49$) is above $UCL(R)$. After deleting subgroup five, the revised averages in Table 1 are calculated and the following first-stage short-run control chart factors are obtained from Table A4 in [11] (for $m = 4$ and $n = 4$): $A_2^{**} = 0.78832$, $D_4^{**} = 2.07041$, and $D_3^{**} = 0.11848$. Revised first-stage short-run control limits are calculated as follows: $UCL(R) = 2.07041 \times 0.1475 = 0.30539$, $LCL(R) = 0.11848 \times 0.1475 = 0.01748$, $UCL(\bar{X}) = 1.278125 + 0.78832 \times 0.1475 = 1.39440$, and $LCL(\bar{X}) = 1.278125 - 0.78832 \times 0.1475 = 1.16185$. Since none of the remaining values plot out of control (i.e., control has been established), the next step is to construct second-stage control limits using the following second-stage short-run control chart factors from Table A4 in

[11] (for $m = 4$ and $n = 4$): $A_2^* = 1.01772$, $D_4^* = 2.94060$, and $D_3^* = 0.09281$. Second-stage short-run control limits are calculated as follows: $UCL(R) = D_4^* \times \bar{R} = 2.94060 \times 0.1475 = 0.43374$, $LCL(R) = D_3^* \times \bar{R} = 0.09281 \times 0.1475 = 0.01369$, $UCL(\bar{X}) = \bar{\bar{X}} + A_2^* \times \bar{R} = 1.278125 + 1.01772 \times 0.1475 = 1.42824$, and $LCL(\bar{X}) = \bar{\bar{X}} - A_2^* \times \bar{R} = 1.278125 - 1.01772 \times 0.1475 = 1.12801$. These control limits may be used to monitor the future performance of the process.

The two-stage short-run control charting methodology has advantages over the other short-run control charting methodologies. It overcomes their reliance on the common rule of thumb, their use of parameter estimates that are not representative of the process, their assumption that the process starts in-control, and their complex implementation. A disadvantage of the two-stage short-run control charting methodology is its recently investigated issue (see [18, 19]) regarding the dependence between the events that the i th and j th plotted values ($i \neq j$) plot outside the same estimated control limit.

Conclusion

This research with two-stage short-run control charts has resulted in a more comprehensive and industry-accessible methodology for control charting in short-run situations. Consequently, opportunities exist to more fully integrate this methodology with other control charting procedures, namely, multivariate and fuzzy control charting. These particular integrations are beneficial because situations where data is short-run can occur in conjunction with multivariate and fuzzy data.

MATTHEW E. ELAM

Control Charts for Batch Processes

Introduction

Batch processing in manufacturing can be described as the simultaneous processing of materials or semifinished units that have been grouped together as a single processing entity. Numerous industries rely on batch processing of one kind or another, including some as diverse as specialty chemicals, pharmaceuticals, food products, fabrics, metals, bakeries, semiconductors, and pulp and paper manufacturers. Distinguishing features of batch processing include the following:

1. A setup of the process occurs during which a recipe of materials or group of units is loaded or “charged” into the processing equipment (e.g., vessel, oven, tank, furnace, reactor).
2. Process input variables (X ’s) such as temperature and pressure are ramped up or down to specified conditions following particular time-oriented “trajectories”.
3. The batch is processed over time frames that may be relatively lengthy, from hours to days, or even longer. This constraint is often the motivation for the utilization of batch processing over single-unit processing.
4. Upon completion, the product material is discharged, and the processing equipment may require cleaning and/or maintenance before the next batch is commenced.

Typically, measurements of product quality characteristics (Y ’s) on samples of the product taken from the batch are then obtained. Usually, these measurements are conducted off-line using gauges or test equipment that may be located nearby or in a remote location (e.g., outside laboratory), and there may be numerous characteristics (Y ’s) that require control within tight specification limits. Because such measurements and tests usually cannot be made until the product is accessible, an additional feature of batch processing is the following.

5. Product quality characteristics are often obtained so late relative to the possible occurrence of

process disturbances or “special cause” variation (see **Assignable Cause; Control Charts, Overview**) as to render them useless in identifying quality problems with the affected batch. Moreover, these causes may lead to unacceptable quality of subsequent batches if the cause system is not understood and remedies applied in a timely manner. Because an unacceptable batch may comprise a large amount of product, the financial impact of a poorly controlled batch process on a manufacturing operation can be substantial.

In *discrete manufacturing* batch processing involves the grouping of processing units (parts) from prior steps in the manufacturing process into a batch or “load”. The load of parts is then processed simultaneously. Examples include the deposition of thin films on substrates (wafers) loaded onto “boats” in a diffusion furnace in semiconductor manufacturing, or the heat treating of metal castings in an oven in an investment casting operation. In the steps prior to the batch-processing step, the wafers (or castings) were the processing units. In *continuous manufacturing* the batch process will operate somewhat differently. A recipe of materials (e.g., solid and liquid feedstocks, chemical additives, recycled stock, etc.) is supplied to the batch vessel, where the batch is processed under controlled conditions as described earlier. Generally, there are no prior subunits that have been assembled into one processing entity, as in discrete manufacturing.

Issues in Applications of Control Charts

Since a batch process by definition repeats itself batch to batch, the batch is the primary processing unit, whether formed from groups of discrete units or from mixed streams of feedstocks, chemicals, and so on, in a continuous batch process. However, a secondary processing unit that must be taken into account is the within-batch unit (e.g., wafer or casting or, perhaps, location in a vessel or tank). This requirement is particularly true if measurement of the Y ’s requires sampling of the within-batch secondary units. Therefore, there are two sources of common cause variation and must be accounted for in the Y ’s, batch-to-batch variation from sampling the primary units and within-batch variation from sampling the secondary units. Control chart users must take this

2 Control Charts for Batch Processes

reality into account when they design control charts and select the rational subgroup for a batch process (see **Control Charts, Overview**; **Control Charts, Selection of**).

In discrete manufacturing, where Shewhart-type charts are commonly applied, a common mistake made by SPC practitioners is to assume that n samples of the within-batch secondary units represent a rational subgroup of size n , followed by the application of $\bar{X}$ -bar and R or S charts to the resulting data. The “subgroup of size n ” assumption is based upon two erroneous notions: (a) that the within-batch variation accounts for all of the common cause variation in the process, which is not valid because the batch-to-batch variation is absent and (b) that n independent primary units (repetitions) have been selected from the process. As expected, the resulting charts have unduly narrow control limits that signal that the process is seriously out of control with respect to mean Y . Consider in Figure 1 an example of an $\bar{X}$ -bar chart of three measurements of a critical dimension (CD) at three sites on 74 wafers from a semiconductor manufacturing operation [1].

The chart exhibits chronic out-of-control behavior; however, the subgroup of size 3 is improper, given that the CD measurements are taken from three sites on the same processing unit (wafer), not from three independently produced processing units.

Two options are available to the control chart user

to address this problem. First, if the within-batch sampling is constant from batch to batch, location and dispersion statistics (e.g., mean and standard deviation) can be calculated from the set of n measurements and considered as overall single measurements of batch “performance”. The location metric represents overall batch quality while the dispersion metric represents within-batch variability or “uniformity”. Individuals charts can then be applied to these batch-level individual measurements ([2, 3], as well as [1] for a case study of this approach). Consider an individuals chart of the CD data in Figure 2.

Note that the control limits are much wider than those of the chart depicted in Figure 1. The fact that the batch-to-batch variability is included in, rather than absent from, the estimate of the common cause variability provided by the average moving range explains the difference. (Moreover, the batch-to-batch variability exceeds the within-batch variability, which only exacerbates the deficit.)

A second approach is to calculate the *variance components* of the overall common cause variation in the measurements through a *nested design* supplied by the batch-to-batch and within-batch samples. Assume that from each of n randomly sampled batches, m random within-batch samples are taken. If the within-batch samples are independent,

Figure 1 X-bar chart of CD measurements

Figure 2 Individuals chart of mean CD

the variance of the mean of the m within-batch measurements is estimated as below (see [2, 4]).

$$\hat{\sigma}_{\bar{x}}^2 = \hat{\sigma}_B^2 + \frac{\hat{\sigma}_W^2}{n} \quad (1)$$

where $\hat{\sigma}_B^2$ = estimated batch variance and $\hat{\sigma}_W^2$ = estimated within-batch variance.

Standard “ 3σ ” control limits for the batch average are given by

$$\bar{\bar{X}} \pm 3 \left(\hat{\sigma}_B^2 + \frac{\hat{\sigma}_W^2}{n} \right)^{1/2}$$

This approach allows for the possibility of varying sample sizes from batch to batch, as well as the introduction of additional components of variability, should that be necessary. Control charts of the within-batch component of variance can also be applied, if desired [2]. If the within-batch variability is random, the standard S chart should suffice; if the variability is nonrandom, however, other control chart schemes may be necessary (e.g., individuals charts on S or a suitable nonlinear transform, S^*).

Use of Multivariate Control Charts

High-quality products are commonly described by more than a few quality characteristics (Y 's), each of

which must be controlled within tight specifications to maintain customer satisfaction. For example, at a polishing process during silicon wafer manufacturing, removal rate, thickness uniformity, and surface quality must be maintained. In paper processing, basis weight, moisture content, and tensile strength, among other properties of the paper must be controlled by the process.

Consider a series of j quality characteristics ($Y_1, Y_2, Y_3, \dots, Y_j$) that are measured on each processing unit (batch). Traditionally, univariate-type control charts (individuals, exponentially weighted moving average (EWMA), cumulative sum (CUSUM), etc.) have been applied to each of the Y_i 's. Two practical issues arise when doing so.

1. A proliferation of control charts to maintain and evaluate can result. This scenario is particularly serious if the manufacturer has different customers who receive products with different target values for each Y_i , and control charts are kept for each Y_i /customer combination. As a consequence, there are manufacturing organizations where thousands of univariate control charts are supposed to be kept and monitored.
2. The Y_i 's are likely to be correlated, in which case, true out-of-control conditions may be overlooked by the assessment of the collection

4 Control Charts for Batch Processes

of individual charts (*see Multivariate Control Charts Overview* and [5] for further discussion).

An answer to this dilemma is the multivariate control chart based upon Hotelling's T^2 statistic. The T^2 statistic collapses the vector of j variables $Y = (Y_1, Y_2, Y_3, \dots, Y_j)$ into the scalar value below

$$T^2 = (Y - \mu)'S(Y - \mu) \quad (2)$$

where $\mu = (\mu_1, \mu_2, \dots, \mu_j)$ is the vector of "expected values" for Y , and S = the observed **covariance** matrix, estimated when Y is "in control". For a complete description of this chart and its application to batch processes, *see Multivariate Control Charts Overview, Hotelling's T^2 Chart* [6, 7].

Consider the CD data analyzed earlier, but imagine that instead of three measurements of the same characteristic, CD, each Y_i is a separate and distinct quality characteristic. The correlation matrix (*see Correlation*) is given below and demonstrates that there are significant pairwise correlations between the three Y 's, an important feature of the data of which the T^2 statistic takes advantage.

1	0.404	0.580
0.404	1	0.388
0.580	0.388	1

A control chart of the T^2 statistic for these data is provided in Figure 3. Clearly, the chart reveals that subgroup #40 is out of control, but in even a more pronounced fashion as compared with that of the individuals chart in Figure 2.

Utilizing the Process Input Variables (X 's)

In recent years, modern manufacturers have installed on-line sensors and gauges, which provide the capability to capture measurements of numerous process input variables (X 's), such as temperature, pressure, line speed, and mixing RPM. MacGregor [5] summarizes the common features of this data. Typically, many more X 's are captured on-line than Y 's are measured in the off-line laboratory. In addition, because these measurements are conducted on-line, they are available instantaneously, while the Y 's can lag by hours. Moreover, the potential sampling rate of these variables is on the order of seconds or less. Finally, the sensors/gauges that capture the X 's do so more precisely and accurately than the gauges used in the laboratory to produce the Y 's. MacGregor [5] also notes that special causes of variation in the Y 's occurring during the batch process generally leave their imprint on the X 's as well. Therefore, massive amounts of relatively cheap and high-quality data may be available in real time on

Figure 3 T^2 chart of three CD measurements

these process inputs (X 's), quite apart from the Y 's captured on each batch. This capability provides the potential to address a serious limitation of batch processing SPC mentioned earlier: the inability to respond to special causes while the batch is being processed.

If such data on process inputs are to be utilized for SPC, then some general characteristics of the data need to be recognized.

1. Data overload will occur. Implementing very high sampling rates of large numbers of X 's will generate massive data, quickly overloading the SPC practitioner, especially if traditional univariate control charts are utilized.
2. Multicollinearity in the X data is likely. Although numerous X 's can be captured, each X cannot be independent of the remaining X 's; in fact, many will be correlated, in some cases highly correlated.
3. Missing data is common. For a variety of reasons data on one or more of the X 's may be missing or invalid (e.g., due to a contaminated or completely failed on-line sensor).

Multivariate Projection Methods

Control charting methods for analyzing and monitoring such data must be able to address these particular features to be effective. A class of methods known as *multivariate projection methods*, which reduce high-dimensional data into low-dimensional "latent variables" have been proposed and successfully applied in recent years (see [8–10]). Statistical projection methods, such as principal components analysis (PCA) and partial least squares or projection to latent structures (PLS) are used to generate the latent variables. Frequently, just a handful of latent variables can explain a large proportion of the variability in a large dataset of intercorrelated variables and, because the latent variables are orthogonal, monitoring each of them is valuable. For example, through the use of PCA a set of k coefficients or "loadings", $\mathbf{P} = (P_1, P_2, P_3, \dots, P_k)$ are generated that linearly combine a set of m variables, $\mathbf{X} = (X_1, X_2, X_3, \dots, X_m)$ into k principal components, $\mathbf{T} = (T_1, T_2, T_3, \dots, T_k)$ or "scores", where $\mathbf{T} = \mathbf{P}^T \mathbf{X}$ (see Figure 4).

These scores can be charted separately or analyzed jointly through the T^2 chart.

Figure 4 Latent variables generated by principal components analysis

Using PLS both the historical X data and Y data are inputs, and the objective of multivariate projection changes to that of extracting the latent variables in the X space that most explain the variation in the Y space. MacGregor and Kourti [11] provide an overview of the PLS methodology. Kourti and MacGregor [9] describe two case studies in which large-dimensional X and Y spaces were reduced through PLS into two- and three-dimensional "scores". These scores can then be monitored via traditional univariate control charts or the T^2 chart.

An additional chart that is recommended is one that monitors the squared prediction error (SPE), the sum of the SPEs of the new observations, $X_{i,\text{new}}$, from the predicted observations, $\hat{X}_{i,\text{new}}$.

$$SPE = \sum_{i=1}^m (X_{i,\text{new}} - \hat{X}_{i,\text{new}})^2 \quad (3)$$

A control chart for SPE that is easy to construct and interpret is recommended by Nomikos and MacGregor [10]. Any value of the SPE above its upper control limit suggests that the process inputs have shifted away from their predicted values. A "contribution plot", similar to a Pareto chart (see **Pareto Chart**), which identifies those X 's that provide the greatest contribution to variability in the "scores", can also be utilized for diagnosis [11]. Kourti and MacGregor [12] discuss how to best monitor and diagnose process variation using the PLS methodology.

Like any other control chart procedure the setup and application of PLS procedures for SPC requires

the availability of historical data from “good” batches (whose processing was subject only to common cause variability). From such data the appropriate PCA/PLS methodology is applied, and the PCA loadings are calculated and stored. (The user must decide how many dimensions of the data (latent variables or “scores”) to utilize.) From these loadings the new observations are calculated, and appropriate control charts are applied to monitor the batch process.

Nomikos and MacGregor [10] also describe an extension of this approach where the X space is three dimensional; in particular, where the X ’s represent measurements from within-batch sampling of time trajectories of process variables (e.g., pressure or temperature) taken over repeated batches. The methodology can be further extended to include values of initial batch setup variables as well. Applying the PLS methodology to the combined sets of data allows monitoring of a batch process in real time.

Conclusions

Batch processing presents challenges to the unsuspecting control chart practitioner. First, typical sampling of a batch for product quality measurement may require that multiple sources of common cause variation be accounted for in the design of the control chart. The issue can be addressed by ensuring that all sources of common cause variability, particularly the batch-to-batch source, are included in the assessment of the process variability used to construct the control limits. In addition, the user must recognize that the design of the chart must account for both primary and secondary unit subgroup sample sizes.

Second, relying on traditional univariate Shewhart-type charts of product quality measurements taken long after the batch is completed may not be an effective control scheme. Many batch processes require relatively long processing times of volumes in which the manufacturer has a significant financial investment. The manufacturer is motivated to monitor a batch in real time so that process disturbances can be identified quickly and midcourse corrections to the batch can be applied, if possible. Modern batch manufacturers routinely collect on-line massive amounts of data on processing conditions that are available for analysis. Multivariate projection methods can be used to compress a large number of these process variables (X ’s) into a small number of latent variables (T ’s)

that account for a high proportion of the variability in output or product quality (Y ’s) when the process is “in control”. Monitoring the latent variables *via* univariate or multivariate control charts that are easy to construct and interpret provides the potential for the user to respond in real time, instead of after the fact, to those special causes that arise as the batch is being processed.

Precontrol

Description of the Method

Precontrol monitors the acceptability of a process by comparing individual process values against their specification limits. Its goal is the prevention of nonconforming units. Precontrol, also referred to as *stoplight control*, classifies measurement data into several groups and monitors the process on the basis of the resulting attribute data. In the case of two-sided tolerance, precontrol lines are drawn at the midpoints between the target and the lower (upper) specification limits. The area between the precontrol limits is referred to as the *green zone*, the areas between the precontrol limits and the specification limits are called the *yellow zones*, and the areas outside the specification limits are referred to as the *red zones*.

Initial process acceptability (capability) is established through a simple setup approval procedure. Five consecutive units are taken from the process, and all five measurements must fall within the green zone for the production to commence. If a single yellow result is observed, additional observations are taken and the count of units falling into the green zone is started anew. If two consecutive yellows or a red are encountered, the process is adjusted (see below) and the approval process is restarted.

Following setup approval, two consecutive units are sampled from the process at periodic intervals. If both units fall into the green zone, or if only one unit falls into a yellow zone, production continues. The process is stopped if both units fall into yellow zones, or if one or more unit falls into a red zone. After stopping the process, one must find the cause of the problem and take action. If both units fall into the same yellow zone, it is likely that the process is off-target. In this case, level adjustments are made using feedback control on the deviations from the target. If consecutive yellows (or reds) are on opposite sides of the target, it is likely that the variability has increased. Causes for the extra variability need to be identified and their occurrence must be prevented in the future. The setup approval stage is repeated after each stop. Five consecutive units must be in the green zone before production can resume.

It is suggested that the frequency of the sampling be set such that the average number of sample pairs between stoppages is about six. For example, if samples are taken every hour and stoppages occur on average every 6 h, the sampling interval is set correctly. The sampling interval should be cut in half if stoppages occur on average every 3 h, and it should be doubled if stoppages occur on average every 12 h.

Several modifications of the basic precontrol technique are discussed in the literature. A two-stage sampling approach that takes an additional sample if the initial sample yields ambiguous results is discussed by Salvia [1]. A modification that replaces the specification limits with control limits (which use the standard deviation of process measurements) is proposed by Gurska and Heap [2].

Historical Note

Precontrol was first described by Satterthwaite [3] who attributes the development of the technique to himself and C.W. Carter, W.R. Purcell, and D. Shainin. The method is described in Bhote [4, 5], Juran and Gryna [6], Shainin [7], and Shainin and Shainin [8].

Example

Bhote [4, p. 228] describes an example that deals with the thickness of certain chrome and gold deposits. For chrome the target thickness is 9 units, with specification limits of 6 and 12, resulting in precontrol limits of 7.5 and 10.5. For gold the target thickness is 32, with specification limits of 23 and 41, resulting in precontrol limits of 27.5 and 36.5, respectively. The data in Table 1 indicate no problems with the capability of the thickness of gold deposits. However, problems are indicated for the thickness of chrome deposits. Two consecutive yellows on the same side of the target are observed on April 4. The first sample on April 5 leads to two consecutive units on opposite sides, while in the second sample one of the observations is in the red zone. The process must be investigated and reasons for the unacceptable results must be found. Often this is easier said than done, as considerable detective work may be required. Bhote makes no mention of how the process was adjusted in this particular example.

2 Precontrol

Table 1 Specification limits. Chrome: 6 and 12. Gold: 25 and 41^(a)

	Unit 1		Unit 2		
	Chrome	Gold	Chrome	Gold	
April 3	9.6	32.0	10.2	30.0	
April 4	10.2	33.0	9.6	33.5	
April 4	10.7	33.5	11.2	35.0	Two yellows on same side (chrome)
April 4	7.6	30.5	8.6	25.4	
April 5	10.5	34.0	6.5	34.5	Two yellows on opposite sides (chrome)
April 5	12.2	30.5	10.2	32.0	One red (chrome)
April 6	7.6	33.5	9.6	35.0	

^(a) Values outside the green zone (7.5 and 10.5 for chrome, and 27.5 and 36.5 for gold) are in boldface

Differences between Precontrol and Control Charts

Both precontrol and control charts take periodic observations from a process. Despite their similarities, the two techniques differ with respect to their objectives. The goal of precontrol is the prevention of nonconforming units. It is an algorithm for controlling a process on its tolerances (without explicit consideration of stability), while control charts monitor the stability of the process over time (without specifically looking at its capability). Control charts (*see Control Charts, Overview*), process capability, and links between control charts and capability (*see Control Charts and Process Capability*) are described in more detail elsewhere.

For very capable processes, a control chart may signal lack of control even though the shifted process is still well within its specifications. It has been argued that in this case control charts are of limited value, as operators would question the wisdom of disturbing a process that produces good items.

Strengths of Precontrol

In situations where processes are highly capable, precontrol offers a simple useful technique for checking the capability of the process. Precontrol reduces the temptation of interfering with processes that are still capable. The procedure will not flag unstable processes as long as they remain capable. The approach has the virtue of drawing management attention only to priority problems.

Precontrol was originally developed with machining operations in mind. There, the operator is faced with the problem of first setting up the machine, and

deciding whether the setup has been done properly and whether the machine is ready for full production. In many machining operations the output variable will drift owing to factors such as tool wear. Simple feedback algorithms that bring the process back to its target are usually possible, and operators with considerable machining experience know how to make these adjustments.

Precontrol (just like control charts) forces the operator to take periodic measurements on a process. Quite often it is not the limits or the zones on these charts that are important, but the fact that process information is obtained. Sudden shifts, trends, cycles, and the presence of overcompensation become visible.

Weaknesses of Precontrol

Precontrol is easy to implement, but its *ad hoc* decision rules on grouped data have led to criticism. In particular, it has been questioned whether the small setup inspection sample size of five consecutive items is able to detect processes with low capability. Furthermore, grouping discards information, and there is a real danger that poor processes slip through the certification stage (Ledolter and Swersey [9]).

Also, there are important reasons why one should worry about process instability even though products are still acceptable. (a) Specifications may change (what is good today may not be good tomorrow); (b) unstable processes may not stay capable for long (within specifications today, but not tomorrow); (c) any deviation from a target, even if the unit is within the specification limits, leads to a loss; and

(4) it is difficult to learn about root causes if a process is not in statistical control.

Precontrol is poorly suited for processes with low capability, as its frequent signals will lead to corrective actions that in the absence of profound process understanding amount to little more than process tampering. Processes with low capability must be improved. This is best done by first making sure that assignable (special) causes of variation have been identified and removed. Typically, this requires a thorough improvement cycle that utilizes control charts as well as other improvement techniques. It would be optimistic to expect that the *ad hoc* adjustments of precontrol can fix the problem. Precontrol alone provides little guidance for process improvement.

Further Discussion

Detailed discussion of the strengths and weaknesses of precontrol can be found in Traver [10], Logothetis [11], Mackertich [12], Ermer and Roepke [13], Steiner [14], Ledolter and Swersey [9], and Ledolter and Burrill [15].

JOHANNES LEDOLTER

Economic Design of Control Charts

Introduction

Control chart design is a problem of practical and academic interest that involves finding the parameters of a control chart that one uses to monitor a stable process. These parameters include the sample size, control limit width, and sampling frequency. Control chart design is a problem of much importance in industry because with good design a firm may ensure that they produce products or services of good quality, or, on the other hand, minimize the costs of producing products or services of poor quality.

There are three general methods used to design control charts for use in practice today. These are designs using a heuristic, statistical design methods, and economic design methods. Another method, called *economic statistical design*, finds designs that meet statistical constraints as in statistical design but, in addition, finds the statistical design that is economically optimal.

In this chapter I will discuss economic and economic statistical design in some detail but I will also provide a little background on the former two methods. My emphasis will be on what practitioners can draw from many years of academic research. I suspect that if one were to rank these methods based upon their popularity in practice, a winner by a large margin would be heuristic design. If the ranking criteria were, however, popularity in the academic literature in statistics, the winner by an equally large margin would be statistical design. The academic literature in production and management science would probably find the economic criterion to be the most popular.

What value, then, does the economic design and economic statistical design literature have in the sense of allowing practitioners to improve their decision making regarding design? My opinion is that the research allows practitioners to actually design charts under an economic or economic statistical criterion were they to develop some method of measuring costs and other system parameters necessary to find a design. I address this problem and give some solutions later in this paper. Furthermore, there has been some recent research that shows that simple Shewhart

type control charts do not have an economic disadvantage over other more complex methods such as likelihood-ratio cumulative sum (CUSUM) charts unless certain conditions are met. In yet other situations, it may be economically optimal to employ methods other than control charts to monitor quality. This research helps to point the practitioner in the right direction in terms of choosing the optimal method, or policy, for maintaining control even if they did not wish to implement an economic design.

The remainder of the chapter is organized as follows: In the second section I provide a review of the literature on control chart design with an emphasis on economic and economic statistical design. The following section outlines how a practitioner may actually use current methods to find economic and economic statistical designs and shows how the recent literature on policy selection may be used. In the last section I provide a summary.

Economic and Economic Statistical Design

The simplest design one could employ is Shewhart's [1] heuristic, which for variable control charts such as the $\bar{X}$ chart, is to choose samples of size 4 or 5 and to use three sigma control limits (see Duncan [2] for an explanation of heuristic control chart design). One then should sample, say, once every hour for high volume processes. This design has desirable behavioral, statistical, and economic characteristics. More specifically, this design is easy to use and understand, works very well in terms of signaling large shifts very quickly, and, in some cases, is close to a minimum cost design. One can improve a heuristic design very easily using a simple formula for the optimal intersample interval (see McWilliams [3]).

Statistical design involves finding the control limit width and the sample size such that the average run length (ARL) in control is high and the ARL is low when the process is out of control (*see Average Run Lengths and Operating Characteristic Curves*). The ARL is the average number of samples taken before a shift is signaled. Statistical design is appealing because the control chart will give few false signals of poor quality when quality is acceptable and will signal a process shift to a state of poor quality relatively rapidly. Woodall [4] discusses statistical design and a thorough treatment of policy selection

2 Economic Design of Control Charts

using statistical criteria is given by Reynolds and Stoumbos [5].

Economic control chart design involves finding the parameters of a control chart such that all of the costs associated with producing a product or service related to **quality** are minimized (*see Cost of Quality*). These costs include the cost of sampling, the cost of searching for false assignable causes of poor quality, the costs of searching for a true **assignable cause** and repairing the system when it occurs, and the cost of producing poor quality products or services. The particular parameters of interest in control chart design are the sample size, the control limit width, and the sampling frequency.

The problem has received much attention in the academic literature. Perhaps the initial thrust in the development of an economic model of a process controlled by a control chart was provided by Girshick and Rubin [6]. Their model provided the basis for many of the practical models that followed but alone it is difficult to implement because of the complex mathematics involved in finding a solution. One of the models owing allegiance to the Girshick and Rubin [6] model is that of Duncan [2].

Duncan [2] developed a model to find the economic design of an $\bar{X}$ chart. He assumed one would use a control chart in the usual way; that is, one takes a sample of size n at regular intervals of h hours and plots the average, or $\bar{X}$ on a control chart with control limits of standardized width k . Some of the important assumptions of the Duncan model are that only a single assignable cause of poor quality will occur; in the literature this assignable cause is called the *expected shift*. (Later findings showed that this assumption is not restrictive in that a single cause model may be a good approximation of a multiple cause model.) There are a number of other models similar to Duncan's including a model provided by von Collani [7] that makes the **estimation** and solution process simpler.

Many other applications to other types of control chart have been done; some examples are the $\bar{X}/R$ combination by Saniga [8], the CUSUM chart by Taylor [9], and the attribute chart by Chiu [10]. Goel [11] compared the economic performance of the $\bar{X}$ chart to the CUSUM chart (*see Cumulative Sum (CUSUM) Chart*).

Lorenzen and Vance [12] provided an extension of the popular Duncan [2] model. This model is more general in the sense that production can continue or

be stopped during a search for the assignable cause and production can be either continued or stopped during repair. Otherwise, the standard assumptions in economic control chart design are made; these are that the time in control follows the negative exponential distribution, a single shift of known size can occur, and the other cost and system parameters are deterministic. The model is defined as follows where C is the expected cost per hour:

$$C = \{C_0/\lambda + C_1(-t + nE + h(ARL_2) + \delta_1 T_1 + \delta_2 T_2) + sY/ARL_1 + W\} \\ \div \{1/\lambda + (1 - \delta_1)sT_0/ARL_1 - t + nE + h(ARL_2) + T_1 + T_2\} + \{(a + bn)/h\} \\ \times 1/\lambda - t + nE + h(ARL_2) + \delta_1 T_1 + \delta_2 T_2\} \\ \div \{1/\lambda + (1 - \delta_1)sT_0/ARL_1 - t + nE + h(ARL_2) + T_1 + T_2\} \quad (1)$$

The terms are as follows:

n = sample size

h = hours between samples

L = number of standard deviations from control limits to center line for the $\bar{X}$ chart

k = reference value for the CUSUM chart

h = decision interval for the CUSUM chart

g = intersample interval

$tt = [1 - (1 + \lambda g)e^{-\lambda g}]/[\lambda(1 - e^{-\lambda g})]$

$s = e^{-\lambda g}/(1 - e^{-\lambda g})$

ARL_1 = average run length while in control

ARL_2 = average run length while out of control

λ = 1/mean time process in control

δ = number of standard deviations slip when out of control

E = time to sample and chart one item

T_0 = expected search time when false alarm

T_1 = expected time to discover the assignable cause

T_2 = expected time to repair the process

δ_1 = 1 if production continues during searches
= 0 if production ceases during searches

δ_2 = 1 if production continues during repair
= 0 if production ceases during repair

C_0 = quality cost/hour while producing in control

C_1 = quality cost/hour while producing out of control ($> C_0$)

Y = cost per false alarm

W = cost to locate and repair the assignable cause
 a = fixed cost per sample
 b = cost per unit sampled.

Without listing any additional articles here, it is safe to write that there are literally hundreds of applications and extensions of the Duncan [2] and Lorenzen and Vance [12] model and other models for economic design appearing in the academic literature in statistics, production, and operations research.

Lorenzen and Vance [12] and Woodall [13–15] among others, have addressed some of the practical shortcomings of using economic designs. These shortcomings include the fact that the designs are hard to determine mathematically, the cost and other system coefficients are difficult to measure accurately, and the solutions are perhaps difficult to implement because they yield designs that have odd intersample intervals (such as sampling every 1.28 h). A related example is one where an economic design allows for an excessive number of false searches or equivalently, a relatively high probability of a false search. Saniga [16] found that Duncan's [2] 25 example problems have type I error probabilities as high as 0.1926. In this case, the excessive number of false searches that would take place might result in users disregarding the signals from the control chart or even adjusting the process when it should not be adjusted, resulting in an increase in common cause variability.

Another problem with economic design is that an optimal solution may yield designs not in accord with modern principles of **quality management** such as those provided by Deming [17] (see **Total Quality Management (TQM)**). Here, optimal solutions might have not only high type I error probabilities but also high type II error probabilities, which would allow defective material or services to be passed on to the consumer. Deming, in essence, proposes that "tight" quality standards such as "make it right the first time" and "eliminate rework" be implemented. (Deming, considering his emphasis on continuous improvement, might not even be in favor of continuous monitoring.) Even contemporary methods such as Six Sigma (see **Six Sigma**) emphasize extremely "tight" quality standards.

These issues as well as others were addressed in a design called *economic statistical design* by Saniga [16]. Here, statistical constraints restricting ARL in control and out of control as well as

the intersample interval were placed upon an economic model. These statistical constraints could be expressed equivalently in terms of the error probabilities or the average time to signal, or ATS. The resulting solution has little of the shortcomings mentioned by Lorenzen and Vance [12] and Woodall [13–15] in that false searches would be limited, short ARLs and short, or even, regular intersample intervals could be ensured. Economical statistical designs would then be in accord with what is required in practice in the sense of providing designs which would meet the behavioral needs of the user as well as the economic and statistical needs of the firm's strategic decision makers.

An additional and unexpected finding of Saniga [16] is that pure statistical designs could be made more restrictive to improve economic performance; certainly a counterintuitive result.

Designing a Control Chart to Minimize Cost

In practice, perhaps the first choice a practitioner must make when he decides to use a control chart to monitor a stable process is to choose an optimal policy. There are three general policies available: do nothing, use a control chart, or use a regular search policy (see **Control Charts for Attributes; Variable Sampling Rate Control Charts; Control Charts, Selection of**). If the choice is to use a control chart, one must choose between any number of alternative control charts. Saniga and Montgomery [18] investigated the performance of alternative methods in a large experiment in which they found the optimal cost solutions for using a variables or attributes control chart, a regular search policy, or simply doing nothing. The last one is called a *never search* policy. While the last was considered an alternative policy it is true that, as Saniga and Montgomery [18, p. 261] mention, "it is difficult to visualize a real-world production system" with system parameters that would deem this policy optimal and "the practical relevance of this policy is questionable". In this work the authors used an $\bar{X}/R$ chart for variables sampling and a fraction defective chart for attributes sampling.

Saniga and Montgomery [18] found that, generally, for detecting small to medium size shifts the $\bar{X}/R$ combination or the regular search policy is economically optimal with the different choices being

based on search time ratios and sampling cost ratios. For larger shifts a fraction defective chart is optimal in three of the four regions investigated. Only if both the search time ratios and sampling cost ratios were low would an $\bar{X}/R$ combination be preferred.

While Saniga and Montgomery [18] address the issue of choosing between variables and attribute Shewhart charts it is also of interest to examine the possibility of using CUSUM charts instead of Shewhart charts. While CUSUM charts are more difficult to design, implement, and use and there is a higher training cost associated with their use, they do have an advantage of providing the optimal ARL for detecting a process shift for any desired in control ARL. Moustakiedies [19] has provided this proof. Assuming a practitioner is interested only in statistical performance, Reynolds and Stoumbos [5] provide some guidelines for **control chart selection** under a wide variety of circumstances. They suggest that one should use a CUSUM or **exponentially weighted moving average** chart (see Lucas and Saccucci [20]) using samples of size 1. Cost and ease of design or use, for example, are not factors considered by the authors. Consider cost for example. If fixed cost is not zero, which is unlikely using any standard method of cost accounting, a policy with $n = 1$ may not be economically optimal unless fixed cost is small. Of course, there are situations where only statistical performance matters and Reynolds and Stoumbos' [5] recommendation would then be very useful.

Looking back at the economic criterion again, Goel [11] found that CUSUM charts did not have an economic advantage over $\bar{X}$ charts unless sample sizes smaller than optimal were employed. Chiu [10] and Von Collani [7] reached similar conclusions about the cost advantages of CUSUMs over $\bar{X}$ charts. The conclusions of Goel, Chiu, and Von Collani, however, were based upon very small experiments.

A thorough investigation of the regions of cost and other system parameter configurations where a CUSUM chart would be preferred to a particular Shewhart chart (the $\bar{X}$) for monitoring the mean of a process was done by Saniga *et al.* [21]. Here, the authors found economic designs for CUSUM charts and for $\bar{X}$ charts for a wide range of system parameter configurations covered in an experimental design. They assumed all costs for using the different control charts would be the same. Since the costs are the same and the CUSUM chart has an advantage in

ARL the CUSUM chart would always be preferred economically. Saniga *et al.* then used regression trees to determine regions where the CUSUM chart had somewhat of an advantage over the $\bar{X}$ chart. They found, for one part of the three part experiment, that if the fixed cost of sampling is small, the expected shift is small and the cost of either a false search or a search for an assignable cause is large an optimal policy is to use a CUSUM chart. For another part of the experiment they found that small fixed costs of sampling lead to CUSUM charts having a decided advantage and, also, the CUSUM chart may be advantageous even for midrange values of the fixed cost if the shift is small and the time to sample and chart an observation is large. Saniga *et al.* [22] also found that a regular search policy is preferred to a control chart for this large experiment for many cases when the fixed costs of sampling are large and the expected shift size is small.

In an earlier related study, Saniga *et al.* [22] found, using a small experimental study, that CUSUM charts are economically preferred to $\bar{X}$ charts when there are restrictions on sample size and sampling interval, when there are statistical constraints on ARL that would occur as in economic statistical design, and when there are two components of variance (*see Variance Components*).

Once the policy decision is made the practitioner needs to estimate the parameters an economic model will require and subsequently, find the optimal design. Estimation of the cost parameters requires some knowledge of cost accounting; a practical presentation of that subject is available in Jones [23]. Some of the other parameters that need to be estimated can be done simply by sampling over time. For example, optimal design involves providing as input the expected search time when a false alarm occurs. A practitioner can record how long each search takes over a period of time and use the mean as input into the economic model. Determination of the expected shift size can be done in a similar fashion; one can record the mean of the distribution of output when a shift occurs. Finding the mean of these means will provide a good estimate of the expected shift. And in a similar manner the other times can be determined.

Finding the actual economic design parameters can be done in a number of ways. Chiu and Wetherill [24] have developed a simple method to determine the design parameters of an $\bar{X}$ chart assuming that the **power** of the control chart is either 0.90 or 0.95. Von

Collani [25] also provides a simple procedure to find the design parameters of a control chart; his method is based upon using a model developed by him rather than the usual Duncan [2] model.

A number of computer programs are also available for finding economic and economic statistical designs. These include that of Montgomery [26], who provided a program allowing a user to find the optimal economic design of an $\bar{X}$ control chart based upon Duncan's [2] model. A program for finding economic, economic statistical, and statistical designs for attribute charts is provided by Saniga *et al.* [27]. Another program by McWilliams *et al.* [28] can be used to find economic, economic statistical, and statistical designs of $\bar{X}/R$ and $\bar{X}/s$ control charts.

The programs mentioned above are readily available, easy to use, and perhaps equally important, permit the user to do a sensitivity analysis of the solution to see what happens when changes to the optimal solution are made; the new solution may meet the needs of the practitioner better than a direct solution.

Summary

Economic and economic statistical control chart designs are some of the several design methods available to users. In this chapter, I have presented some of the background work leading to our current knowledge about these type of designs. I have also provided users with some guidelines (and references) on actually designing and using a control chart under this criterion. Many additional references on the subject exist and are readily available.

Average Run Lengths and Operating Characteristic Curves

Introduction

The average run length (*ARL*) is the expected number of rational subgroups to be collected or the expected number of charting statistics to be plotted on a **control chart** before the first signal is given by the chart. The operating characteristic (*OC*) is the probability that no signal will be given by a chart on the first subsequent sample following a shift and thus failing to detect the shift. Both the *ARL* and the *OC* are measures of how quickly a chart will detect a change in the process and can be used to assess how well the chart performs.

The performance of a control chart, however, is tied to how it is designed. The design of a control chart involves, among other things, the choice of a charting statistic, the choice of control limits (whether it is $k\sigma$ control limits or probability limits), the size of the shift to be detected, and the sample or rational subgroup size as well as the frequency of sampling. These issues need to be addressed before a chart can be implemented.

Operating Characteristic

To illustrate how the *OC* can be of help with design ideas, consider the Shewhart $\bar{X}$ control chart (*see Control Charts for the Mean*) with $k\sigma$ limits for monitoring the process mean of a quality characteristic. Assume the quality characteristic follows a **normal distribution** with both the process mean and the process standard deviation known constants, denoted by μ_0 and σ_0 , respectively. Consider the probability of no signal on the $\bar{X}$ control chart when a shift in the mean of the quality characteristic has occurred. Suppose that the shift in the mean is expressed as $\mu_1 = \mu_0 + \delta\sigma_0$, where μ_1 denotes the new mean after the shift and δ is the size of the shift expressed in standard deviation units. This type of a shift is known as a *sustained shift* (or a step shift) in the process mean. This implies that the new process mean is $\delta\sigma_0$ units different (higher or lower) from the old process mean

for all future subgroups drawn from the process. The probability of no signal on the $\bar{X}$ control chart, given a sustained shift in the process mean, is calculated as

$$\begin{aligned}
 &P(\text{No signal/Shift in process mean}) \\
 &= P\left(\mu_0 - k\frac{\sigma_0}{\sqrt{n}} < \bar{X}_i < \mu_0 + k\frac{\sigma_0}{\sqrt{n}} \mid \mu_1 = \mu_0 + \delta\sigma_0\right) \\
 &= P(-k - \delta\sqrt{n} < Z_i < k - \delta\sqrt{n}) \\
 &= \Phi(k - \delta\sqrt{n}) - \Phi(-k - \delta\sqrt{n}) \\
 &= \beta(k, \delta, n), \text{ say.} \tag{1}
 \end{aligned}$$

This last probability is the *OC* (or β -risk as it is sometimes called) and is a function of three things: the distance of the control limits from the centerline k , the size of the shift δ , and the sample size n . The *OC* is therefore a useful tool to understand a chart's ability to detect a shift δ and simultaneously study the influence of k and n . In the **quality control** environment, however, the sample size n and charting constant k are typically fixed or prespecified so that it is common to use the plot of $\beta(k, \delta, n)$ as a function of δ . This plot is called the *operating characteristic curve* or the *OC curve* and lets us see what effect the process shift δ has on the chart's performance.

Example 1: Assume that the traditional 3σ control limits (or alternatively, 0.00135 probability limits) are used and detecting a shift of size 1.5 is of interest with samples of size $n = 5$. If the process is in control, $\delta = 0$ and the probability of no signal is found by substituting $k = 3$, $\delta = 0$, and $n = 5$ in $\beta(k, \delta, n)$, which yields $\beta(3, 0, 5) = 0.9973$. When a process shift of size 1.5 occurs, the probability of no signal is found by substituting $k = 3$, $\delta = 1.5$, and $n = 5$ in $\beta(k, \delta, n)$. This yields 0.362.

Figure 1 illustrates the *OC* curve where 3σ control limits and samples of size 5 are used. Thus, we are considering the value of $\beta(3, \delta, 5) = \Phi(3 - \delta\sqrt{5}) - \Phi(-3 - \delta\sqrt{5})$ as δ changes. This allows us to observe the influence of the size of the shift on the probability of no signal over a range of values. Note that there is a second horizontal axis showing the process mean for easier interpretation.

On the *OC* curve the β -risk is plotted on the vertical axis for a given δ on the lower horizontal

Figure 1 OC curve of an $\bar{X}$ control chart when $k = 3$ and $n = 5$

axis. Because the β -risk is, in fact, a probability and since 3σ control limits are used, the value for the β -risk varies between 0 (when $\delta \rightarrow \infty$) and 0.9973 (when $\delta = 0$). In addition, the upper horizontal axis shows the process mean μ_1 . The relationship between the lower and the upper horizontal axis is linear and is given by $\mu_1 = \mu_0 + \delta\sigma_0 = 20 + \delta 0.5$. However, we mainly focus on the relationship between the β -risk and δ (or the size of the shift in the process mean) and not on the process mean itself.

We can see that as the process mean moves further away from the known in-control value of 20 (when $\delta = 0$) the β -risk decreases. Thus, the larger the sustained shift in the process mean, the smaller the probability that the sample mean (or charting statistic) will plot between the upper control limit and the lower control limit, or alternatively, give no signal. This is a good thing.

As an alternative to the OC curve, we can graph the probability of a signal $1 - \beta(k, \delta, n)$ given that a sustained shift in the process mean has occurred. When substituting $\delta = 0$ in $1 - \beta(k, \delta, n)$ we obtain the false alarm rate (FAR), i.e. the probability of a signal when no shift occurred. In this case, $1 - \beta(3, 0, 5) = 0.0027$. If, however, a process shift of size 1.5 occurs the probability of a signal is $1 - \beta(3, 1.5, 5) = 1 - 0.362 = 0.638$. Therefore, if the process mean has either increased or decreased by 1.5 standard deviations the probability of a signal is no longer 0.0027 but 0.638.

Figure 2 Probability of a signal of an $\bar{X}$ control chart when $k = 3$ and $n = 5$

Figure 2 indicates how the probability of a signal increases as the size of the sustained shift increases. Intuitively an increase in the probability of a signal (or on the other hand, a decrease in the probability for no signal) was expected.

It is interesting to note the similarity between the probability of a signal on an $\bar{X}$ control chart, i.e. $1 - \beta(k, \delta, n)$ as a function of δ and the **power** $\pi(\delta)$ of a test for the null hypothesis $H_0: \mu = \mu_0$ against the alternative hypothesis $H_1: \mu \neq \mu_0$. The test is based on the (test) statistic $Z = \frac{\sqrt{n}(\bar{X} - \mu_0)}{\sigma_0}$ and we reject H_0 in favor of H_1 if $|Z| \geq k$. Now if we assume that $\mu = \mu_0 + \delta\sigma_0$ and calculate the power of this test as a function of δ , we find

$$\begin{aligned} \pi(\delta) &= 1 - \beta = 1 - P(|Z| < k | \mu = \mu_0 + \delta\sigma_0) \\ &= 1 - \Phi(k - \delta\sqrt{n}) + \Phi(-k - \delta\sqrt{n}) \end{aligned} \quad (2)$$

which is of course the probability of a signal $1 - \beta(k, \delta, n)$ obtained earlier.

The OC curve (or, equivalently, the probability of a signal) can also be used as a tool to compare control charting plans. Suppose that an operator would like to compare two control charting plans to monitor the process mean. Both plans use the $\bar{X}$ control chart with 3σ control limits but the first plan uses $n = 5$ taken every 30 min, whereas the second plan uses $n = 6$ taken every 30 min. The question is then what the effect of sampling an extra unit is. The OC curves for both these plans are displayed in Figure 3 with

Figure 3 OC curves for (a) plan 1 with $n = 5$ and (b) plan 2 with $n = 6$ for varying δ

Figure 4 The probability of a signal for (a) plan 1 with $n = 5$ and (b) plan 2 with $n = 6$ for varying δ

the accompanying probabilities of a signal (or $1 - \beta(k, \delta, n)$) shown in Figure 4. In addition, Table 1 lists some values of $\beta(k, \delta, n)$ and $1 - \beta(k, \delta, n)$ for various values of δ .

We see that the second plan has a consistently lower β -risk and a higher probability of a signal for all values of δ . Therefore, if the objective is to detect a shift in the process mean as soon as possible and one can afford the extra cost of sampling, plan 2 will be preferred. In the language of **hypothesis testing**,

this shows that with all other things being equal, the power of a test to detect a shift is higher for a larger sample size.

Because the OC curve and the probability of a signal, given a shift in the process, do not tell the entire story, perhaps a more popular method to evaluate and examine the performance of control charts or make comparisons between control chart plans, is the run-length distribution.

Run-Length Distribution and the Average Run Length

The number of rational subgroups to be collected or the number of charting statistics to be plotted on a control chart before the first out-of-control signal is observed, is the run length of a chart. The discrete random variable defining the run length is called the *run-length random variable* and typically denoted N . The distribution of N is called the *run-length distribution*.

Characteristics of this distribution give the user more insight into the performance of a chart. These characteristics are, for example, its **moments** such as the expected value and standard deviation as well as **percentiles** or **quartiles**.

If no shift occurred ($\delta = 0$) the distribution of N is referred to as the *in-control run-length distribution*. In contrast, if the process did encounter a shift ($\delta \neq 0$) the distribution of N is labeled the out-of-control run-length distribution. To distinguish between these two situations the notations N_0 and N_δ are used. This notation is also used for the characteristics of the run-length distribution.

Assuming that the random samples are independent and that the probability of a signal is the same for all samples (or time points), the run-length distribution is given by

$$P(N = j) = \beta(k, \delta, n)^{j-1} (1 - \beta(k, \delta, n)),$$

$$j = 1, 2, 3, \dots \quad (3)$$

where $\beta(k, \delta, n)$ is the probability of no signal defined in equation (1). This distribution is easily recognized as the geometric distribution with probability of success $1 - \beta(k, \delta, n)$ so that we write, symbolically, $N \sim \text{Geo}(1 - \beta(k, \delta, n))$. The success probability is the probability of a signal or the signal probability and this probability completely characterizes the geometric (run length) distribution.

Table 1 The probability of no signal and the probability of a signal for two competing control chart plans

δ	Probability of no signal		Probability of a signal	
	$\beta(3, \delta, 5)$	$\beta(3, \delta, 6)$	$1 - \beta(3, \delta, 5)$	$1 - \beta(3, \delta, 6)$
0	0.9973	0.9973	0.0027	0.0027
0.25	0.9925	0.9914	0.0075	0.0086
0.50	0.9701	0.9621	0.0299	0.0379
0.75	0.9071	0.8776	0.0929	0.1224
1.00	0.7775	0.7090	0.2225	0.2910
1.25	0.5812	0.4753	0.4188	0.5247
1.50	0.3616	0.2501	0.6384	0.7499
2.00	0.0705	0.0288	0.9295	0.9712
2.25	0.0211	0.0060	0.9789	0.9940
2.50	0.0048	0.0009	0.9952	0.9991
2.75	0.0008	0.0001	0.9992	0.9999
3.00	0.0001	0.0000	0.9999	1.0000

As mentioned, various statistical characteristics or summary measures of the run-length distribution provide insight into how a control chart functions and performs. Remember that we want the chart to signal a shift or a change quickly when a change takes place and not signal too often when the process is actually in control, which is when no shift or change has taken place. We are interested in the typical value as well as the spread or the variation in the run-length distribution. A popular measure of the typical or the central tendency of a distribution is the expected value or the mean or the average. Accordingly, this has been the most popular index or measure of a typical chart performance, called the *average run length (ARL)*. Therefore, as stated before, the *ARL* of a control chart is the expected number of subgroups that must be collected before the control chart signals for the first time. In other words the *ARL* is the expected waiting time for the first signal. When the process is actually in control, the expected number of subgroups that must be collected before the control chart signals (erroneously) for the first time is called the *in-control average run length* and is denoted by ARL_0 . On the other hand, the out-of-control average run length, denoted by ARL_δ , is the expected number of samples to be collected before a control chart signals for the first time, when the process has gone out of control. Obviously, for an “efficient” control chart the in-control average run length ARL_0 should be “large” and the out-of-control average run length ARL_δ should be “small”. Hence, when comparing the performance of two

or more charts the in-control average run length ARL_0 of the charts is usually fixed at an acceptably “high” level so that the number of false alarms or the *FAR* is reasonably “small”. The chart with the smallest or lowest out-of-control average run length ARL_δ for a change or shift of a specified size δ in the process parameter is then selected to be the winner.

From the properties of the geometric distribution the *ARL* for the chart is the expected value of N , therefore $ARL = E(N) = [1 - \beta(k, \delta, n)]^{-1}$.

Therefore, when the signaling events are independent and have the same probability, the *ARL* of the chart is simply the reciprocal of the probability of a signal. It is this simple relationship between the *ARL* and the probability of a signal (or, probability of no signal) that accounts for their popularity as measures of a control charts’ performance.

It is seen that the *ARL* is also a function of k , δ , and n and for the Shewhart $\bar{X}$ chart,

$$ARL(k, \delta, n) = [1 - \Phi(k - \delta\sqrt{n}) + \Phi(-k - \delta\sqrt{n})]^{-1} \quad (4)$$

Consequently, the *ARL* can and often is also used to compare two or more control chart schemes or plans.

Example 2: Suppose we have to choose between the two competing control chart plans from Example 1 using the *ARL* as the performance measure. The *ARL* (for various δ) of both plans are shown in Figure 5 with the *ARL* on the vertical axis and

the size of the shift δ on the lower horizontal axis together with the actual process mean on the upper horizontal axis. The most efficient control chart plan is clearly the one for which the ARL is the smallest, given a particular shift in the process mean.

From Table 2, for instance, we see that if $\delta = 0.5$ then plan 2, with $ARL(3, 0.5, 6) = 26.36$, which uses $n = 6$ observations at each sampling stage, is preferred to plan 1 with $ARL(3, 0.5, 5) = 33.40$. On the other hand, from Table 2 it is seen that if $\delta \geq 2.5$

Figure 5 ARL for (a) plan 1 with $n = 5$ and (b) plan 2 with $n = 6$ for varying δ

Table 2 The average run lengths for two competing control chart plans

δ	Plan 1 $ARL(3, \delta, 5)$	Plan 2 $ARL(3, \delta, 6)$
0	370.38	370.38
0.25	133.16	115.87
0.50	33.40	26.36
0.75	10.76	8.17
1.00	4.50	3.44
1.25	2.39	1.91
1.50	1.57	1.33
1.75	1.22	1.11
2.00	1.08	1.03
2.25	1.02	1.01
2.50	1.00	1.00
2.75	1.00	1.00
3.00	1.00	1.00

then either plan 1 or plan 2 may be used since their ARL s are basically equal, i.e. $ARL(3, \delta, 5) \approx ARL(3, \delta, 6) \approx 1$ for $\delta \geq 2.5$.

Note that in order to compare two control chart plans, it is customary to fix the in-control average run length (ARL_0) at some specified or desirable value – in this case 370.38. This was also done in Example 1 when we used $\beta(k, \delta, n)$ and $1 - \beta(k, \delta, n)$ – see Table 1. Although the OC and the ARL enable us to compare different control chart plans, using this approach has a drawback – there is a trade-off between the low occurrence of false alarms and the fast detection of a process change. But, because the OC and the ARL can be used to compare different types of control chart designs (such as the Shewhart, cumulative sum (CUSUM) (see **Cumulative Sum (CUSUM) Chart**), exponentially weighted moving average (EWMA) (see **Exponentially Weighted Moving Average (EWMA) Control Chart**) etc.), which is valuable, this drawback is almost entirely overshadowed.

Other characteristics of the run-length distribution are also of interest. For example, in addition to the mean, one should also look at the standard deviation of the run-length distribution to get an idea about the variation. Using results for the geometric distribution, the standard deviation of the run length, denoted by $SDRL$, is given by

$$SDRL(k, \delta, n) = \sqrt{\beta(k, \delta, n) [1 - \beta(k, \delta, n)]}^{-1} \quad (5)$$

Since the geometric distribution is skewed (to the right) the mean and the standard deviation become questionable measures of central tendency and spread. Other descriptive measures can be more useful. For example, the percentiles such as the median and the quartiles can provide valuable information both about the typical as well as the variation in the run-length distribution. Since the run-length distribution is discrete, the $100^{\text{th}} p$ th percentile ($0 < p < 1$) is defined as the smallest integer j such that the cumulative probability is at least p , that is $P(N \leq j) \geq p$. The median is the 50th percentile so that $p = 0.5$ and the first quartile is the 25th percentile, so that $p = 0.25$. For example, we calculate the following cumulative probabilities for the run-length (geometric) distribution for a signaling probability of 0.2 (Table 3).

Hence, the first quartile of the run-length distribution is 2, the median is $-\log(2)[\log(0.8)]^{-1} = 3.1$,

Table 3 Cumulative probabilities of the run-length distribution for signal probability 0.2

j	1	2	3	4	5	6	7	8	9
$P(N \leq j)$	0.2000	0.3600	0.4880	0.5904	0.6723	0.7379	0.7903	0.8322	0.8658

i.e. 4 and, the third quartile is 7. For the same distribution, the ARL is $0.2^{-1} = 5$ and the standard deviation is $\sqrt{0.8 \times 0.2^{-1}} = 4.47$. The interquartile range equals $7 - 2 = 5$ which is perhaps a better indicator of the spread than the standard deviation.

In the case of other Shewhart-type control charts such as the S^2 , S , R , p , np , c , and u charts the run-length distribution is also geometric with the probability of success equal to the probability of a signal, i.e. $N \sim \text{Geo}(P(\text{Signal}))$. Therefore, as with the $\bar{X}$ we can again use the OC curve and the ARL as a function of the process shift to measure the performance of these control charts. All we need is basically the probability of a signal or, alternatively the probability of a signal. One should note that computing the OC values or ARL for monitoring schemes that combine information over time (e.g. CUSUM and EWMA control charts) or for charts monitoring autocorrelated data can be problematic. In such cases, simulation has proven useful in approximating run-length distributions.

Other Performance Measures

Two other measures of performance of a control chart are the average time to signal (ATS) and the number of individual items that have been produced or inspected I .

If samples are taken over equally spaced time intervals the ATS is given by $ATS = ARL \cdot h$ where h is the time between any two successive samples. Thus, the ATS is the average number of time periods until a signal is generated on the control chart.

The ARL can also be expressed as the number of individual items that have been inspected I , rather than the number of samples taken. If the samples are all of size n , I is given by $I = ARL \cdot n$.

In practice, however, where control charts are often designed for a very specific process or system, evaluating the performance of a control chart can be more difficult and time consuming than what has been presented in the foregoing discussion. A more in-depth analysis of the performance of Shewhart control charts is then typically needed.

Acceptance Sampling and OC Curves

In **acceptance sampling**, for instance, the OC curve is not similar to that of a Shewhart-type of control chart. Instead, for any given fraction nonconforming p in a submitted lot, the OC curve shows the probability P_a that the lot will be accepted on the vertical axis for a given fraction nonconforming p on the horizontal axis.

The question that acceptance sampling tries to answer is also different i.e. given a submitted lot of products, how can we tell if it is acceptable? There are two options when assessing the quality of lots – 100% inspection or acceptance sampling. The purpose of acceptance sampling is to determine whether a submitted lot is likely to contain “acceptable” or “rejected” products based on a random sample only. This involves taking one or more samples from a lot and is generally cheaper than 100% inspection – especially when **destructive testing** is needed. Each item in the sample(s) is then measured or otherwise evaluated and ultimately classified as “accepted” or “rejected”.

The simplest type of sampling plan involves a single sample. However, more advanced procedures, for example, double sampling, multiple sampling, and **sequential sampling**, have also been developed. In judging the diverse choice of sampling plans it is desirable to compare their performance over various quality levels. OC curves serve this purpose.

Ideally, we want a sampling plan that would make the correct decision between good and bad lots 100% of the time. This ideal OC curve will therefore always accept the lot when the actual fraction nonconforming is at or below the acceptable quality level (AQL) and it will always reject the lot when the actual fraction nonconforming is above the AQL . The probability of acceptance will equal one until the AQL is reached. At this point the curve drops vertically from a probability of acceptance of one to a probability of acceptance of zero. Hereafter, the probability of acceptance will equal zero. The ideal OC curve is illustrated in Figure 6.

Figure 6 Ideal OC curve with $AQL = 0.01$

Sadly, mistakes will sometimes be made, i.e. bad lots will be accepted or good lots will be rejected and the ideal OC curve can therefore never (or, at most, rarely) be obtained in practice.

OC Curves for Single (Attributes) Sampling Plans

When only one sample is used to declare the acceptability of the lot, the acceptance plan is called a *single-sampling plan* (see **Single Sampling by Attributes and by Variables**). Suppose we needed to inspect a lot of size N which is large (theoretically infinite). A random sample of n items is taken and the number of nonconforming items d is observed. The lot will be accepted if d is less than or equal to an acceptance number c , i.e. the maximum allowable number of nonconforming items in the sample. The probability of lot acceptance is then the probability that d is less than or equal to c , i.e. $P_a = P(d \leq c)$. Because the number of nonconforming items d in a random sample of size n is binomially distributed with parameters n and p , where p denotes the fraction of nonconforming items in the lot, we have that $P_a = P(d \leq c) = \sum_{d=0}^c \binom{n}{d} p^d (1-p)^{n-d}$. The OC curve is obtained if P_a is plotted against p .

Example 3: The probability P_a of no more than $c = 2$ nonconforming items in a sample of $n = 100$, with $p = 0.01$ is $P_a = P(d \leq 2) = \sum_{d=0}^2 \binom{100}{d} 0.01^d \times (1 - 0.01)^{100-d} = 0.92$. This means that if 1% of

the products are nonconforming, the probability of lot acceptance is 0.92. Alternatively, one can interpret this as follows: If 100 lots are submitted from a process that produces 1% nonconforming items it is expected that 92 of the lots will be accepted and 8 will be rejected.

For different choices of n and c the acceptance probability P_a can be calculated similarly, but note that the shapes of the OC curves depend entirely on the choice of n and c . This is shown in Figure 7.

The OC curve basically shows the discriminatory power of the sampling plan. For example, when lots with less than 1% nonconforming items are submitted, they will rarely be rejected, since the probability of acceptance is greater than 0.9 for all plans. However, when lots with more than 6% nonconforming items are submitted, they will almost surely be rejected, since the probability of acceptance is small ($P_a < 0.2$) for all plans. From the slope of the OC curve it is seen that the OC curve approaches the shape of the ideal OC curve as the sample size increases. This implies that the discriminating power of the OC curve increases as sample size increases.

Acceptance sampling plans with $c = 0$, however, are not desirable because the probability of acceptance drops much quicker than for $c > 0$ leading to “easier” rejection of a lot. This is illustrated in Figure 8.

Type-A and Type-B OC Curves

The above-mentioned OC curves are called *type-B*

Figure 7 OC curves of a single-sampling plan^a

Figure 8 OC curves of a single-sampling plan for different sample sizes and $c = 0$

OC curves. In the structure of these OC curves the binomial distribution is the exact probability distribution for calculating the probability of lot acceptance (the Poisson distribution gives a satisfactory approximation). In contrast, in the structure of type-A OC curves the hypergeometric distribution is used for calculating the probability of lot acceptance (the Poisson or binomial distributions often give satisfactory approximations). While type-A OC curves are concerned with the quality of isolated lots (of finite size), type-B OC curves are concerned with the average quality of a stream of lots (theoretically of infinite size). Type-B OC curves can be used to examine a producer's risk, since a producer typically wants to know what percentage of his lots will be rejected by a sampling plan for any quality level. In contrast, type-A OC curves can be used to examine consumer's risk, since a consumer typically wants to know the risk he is taking when accepting a somewhat bad lot.

It is seen from Figure 9 that as the lot size increases, the type-A OC curve approaches the type-B OC curve. So, there is no practical difference between a type-A OC curve with a large lot size and a type-B OC curve (or, the OC curve for infinite lots, as it is sometimes called). In general, if lot size is at least 10 times the sample size ($n/N \leq 0.1$), "a type-B OC curve". Hence, add OC may be taken as a good approximation to a type-A OC curve. Also shown in Figure 9 are type-A OC curves for $n = 20$, $c = 0$, and various lot sizes N . Note that the OC curves for $N = 500$, $N = 100$, and $N = 50$ are very similar. We can conclude that the lot size has a decreasing effect

Figure 9 Comparisons of OC curves for different sampling plans

on the OC curve as it increases.

For a given lot fraction nonconforming, the probability of acceptance calculated for a finite lot (by using hypergeometric probabilities) is always less than that calculated for an infinite lot (by using binomial probabilities). Therefore, the type-A curve will always lie below the type-B curve (this is also illustrated in Figure 9).

The acceptance probabilities of the type-A OC curves are calculated using an approximation. As illustration, the probability P_a of no more than $c = 0$ nonconforming items in a sample of $n = 20$ taken from a lot of size $N = 50$ with $p = 0.04$ is

$$\begin{aligned}
 P_a &= P(d \leq 0) \\
 &= \sum_{d=0}^0 \frac{pN!}{d!(pN-d)!} \left(\frac{n}{N}\right)^d \left(1 - \frac{n}{N}\right)^{pN-d} \\
 &= \frac{(0.04)(50)!}{0![(0.04)(50)-0]!} \left(\frac{20}{50}\right)^0 \left(1 - \frac{20}{50}\right)^{(0.04)(50)-0} \\
 &= 0.36
 \end{aligned} \tag{6}$$

This means that if 4% of the products are nonconforming the probability of lot acceptance is 0.36.

OC Curves for Double, Multiple, and Sequential Sampling Plans for Attributes

When two samples are used to declare the acceptability of the lot, the acceptance plan is called a *double-sampling plan* (see **Multiple Sampling**

Figure 10 OC curves of a double-sampling plan with $n_1 = 50$, $n_2 = 100$, $c_1 = 1$, and $c_2 = 3$

Plans). Under certain circumstances, a second sample is required before a lot can be accepted or rejected. If the first sample is not good (bad) enough to be accepted (rejected), the decision is based on the first and second samples combined. Let n_1 and n_2 denote the sample sizes of the first and second sample, respectively. Let c_1 and c_2 denote the acceptance number of the first and second sample, respectively. The procedure of a double-sampling plan is as follows. The first sample of size n_1 is examined from a lot of size N . The lot is accepted if the sample contains c_1 or less nonconforming items. The lot is rejected if the sample contains more than c_2 nonconforming items. The second sample of size n_2 is examined if the first sample contained more than c_1 , but less than or equal to c_2 nonconforming items. The lot will be accepted if the combined sample contains c_2 or less nonconforming items; otherwise it will be rejected (Figure 10).

When three or more samples are used to declare the acceptability of the lot, the acceptance plan is called a *multiple-sampling plan*. The procedure of a multiple sampling plan follows. If the number of nonconforming items is less than or equal to some acceptance number, the lot is accepted. However, if the number of nonconforming items is greater than or equal to some rejection number, the lot is rejected. Otherwise, another sample is taken until the final sample is taken where a decision about the acceptability of the lot must be made. When the

acceptance plan allows for a decision each time a new item is inspected, it is called a *sequential sampling plan*.

Profile Monitoring

Introduction

Profile monitoring is the use of **control charts** for cases in which the quality of a process or product can be characterized by a functional relationship between a response variable and one or more explanatory variables. These cases appear to be increasingly common in practical applications. For each profile we assume that n ($n > 1$) values of the response variable (Y) are measured along with the corresponding values of one or more explanatory variables (the X s). The reader is referred to Woodall *et al.* [1] for a more detailed and comprehensive review of profile monitoring methods. This is a relatively new area of application, so no software is known to be available for its implementation.

Jin and Shi [2] and Zhou *et al.* [3] used the term *waveform signals* to refer to what we call *profiles*. These signals are often collected by sensors during manufacturing processes, e.g., tonnage stamping in stamping, torque signals in tapping, and force signals in welding. Gardner *et al.* [4] used the term *signature* in place of our use of *profile*.

Calibration processes are often characterized by linear functions, as discussed by Mestek *et al.* [5], for example. The profile monitoring framework also includes applications in which numerous measurements of the same variable, e.g., a dimension such as thickness, are made at several locations on each manufactured part.

In many cases it is most efficient to summarize the in-control performance with a parametric model and monitor for shifts in the parameters of this model. The control charts are then based on the estimated parameters of the model from successive profiles observed over time. For nonparametric models one can alternatively monitor metrics that reflect the discrepancies between observed profiles and a baseline profile established using historical data.

Some General Issues

Phase I Applications

In phase I, one analyzes a historical set of process data. The goals in phase I are to understand

the variation in a process over time, to evaluate the process stability, and to model the in-control process performance. With profile data collected for phase I, one should examine the fit of the hypothesized model for each profile. One should check, for example, for **outliers**. In some cases it may be more appropriate to delete specific points within a profile dataset rather than to discard the entire profile sample.

The principal component analysis, as described by Jones and Rice [6], can be very useful in summarizing and interpreting a set of phase I profile data with identical, equally spaced values of an independent variable X for each profile. With this approach one treats each profile as a multivariate vector of n response Y values and identifies a few mutually orthogonal linear combinations of the Y variables that explain as much variation in the profiles as possible. If these principal components are interpretable, this approach can be very effective in understanding process performance. Jones and Rice [6] recommended plotting the average profile and the profiles with the largest and smallest principal component scores for aiding in the interpretation of the principal components.

Model Selection

Any model selected for a particular application should be as simple as required to adequately model the profile data. Standard recommendations regarding model selection apply. With any model, however, it must be determined how to design a monitoring procedure to detect profile changes over time most effectively, preferably in a way that allows for the interpretation of out-of-control signals.

It is critically important to assess variation between profiles in phase I as well as variation within profiles. Common cause variation is that variation considered to be characteristic of the process and that cannot be reduced substantially without fundamental process changes. It must be determined how much of the profile-to-profile variation is common cause variation and should be incorporated into the determination of the control chart limits to be used for monitoring in phase II. There is common cause variation between profiles if it is not reasonable to expect each set of observed profile data to be adequately represented using the same set of parameters for the assumed model. Process knowledge is always

required in the decision whether or not to include profile-to-profile variation as common cause variation. From our experience, it is often unrealistic to expect that process improvement can be used to remove all profile-to-profile variation.

The Control Chart Statistic(s)

In phase II it is often recommended to monitor the profiles using a separate control chart for each parameter of a parametric model, provided the estimators of the parameters at each sampling stage are independent. If the estimators of the parameters of the model for the profile are dependent, as is more often the case, one can use a T^2 chart (see **Hotelling's T^2 Chart**). It is important to use an appropriate estimator of the variance–covariance estimator in phase I. In particular, if the vectors of estimators are pooled in order to estimate the variance–covariance matrix, then the resulting T^2 chart will tend to be quite ineffective in detecting outlying profiles or sustained shifts in the profiles over time.

If the approach used is nonparametric, then a reasonable approach is to base control charts on metrics that measure the departures of observed process profiles from a baseline profile model developed in phase I. One such metric is the average deviation of the observed profile from the baseline profile calculated over a grid of X values. Gardner *et al.* [4] recommended this approach.

One should make sure that the choice of statistics to monitor does not result in methods that are unable to detect certain types of profile shifts. For example, if one chooses to monitor only a subset of the principal components, or a subset of wavelet coefficients, that were determined using only in-control data, then certain types of out-of-control profile shifts may be undetectable.

In some cases it may be possible to target control charts to detect specified types of process faults. This can be done by inducing the process faults and observing the effect on several profiles. The control chart statistic can then be determined, perhaps using discriminant analysis, to be most effective in detecting a specific fault. Gardner *et al.* [4], for example, used this type of approach. This strategy reduces the dimensionality of the problem and increases the **power** of the charts, but one must be careful not to overlook important types of process faults.

Analysis of Simple Linear Regression Profiles

In this section we review the work done on the simplest case, the one in which the profile is adequately represented by a straight line.

Phase II Methods

Several researchers have studied phase II control charting methods for monitoring a simple linear regression relationship with assumed known values of the Y intercept, slope, and variance parameters. One approach of Kang and Albin [7] involved a multivariate T^2 control chart based on the successive vectors of the least-squares estimators of the Y intercept and slope. Their second method used statistics based on the successive samples of n deviations from the in-control line with a combination of an exponentially weighted moving average (EWMA) chart (see **Exponentially Weighted Moving Average (EWMA) Control Chart**) to monitor the average deviation and a range (R) chart (see **Moving Range and R Charts**) to monitor the variation of the deviations.

Kim *et al.* [8] proposed alternative control charts for monitoring in phase II. Since they recommended coding the X values so that the estimators of the Y intercept and slope are independent, they monitored each of the two regression coefficients using a separate EWMA chart. Also, they proposed replacing the R chart of Kang and Albin [7] by one of two EWMA charts for monitoring a process standard deviation. The statistical performance of the combined use of these three EWMA charts was shown to be superior to that of the phase II methods of Kang and Albin [7] for sustained shifts in the regression parameters. Their method is also much more interpretable since each parameter in the model is monitored with a separate control chart. One could use other types of control charts, such as individuals and **moving average** control charts (see **Control Charts for the Mean**), with the sequences of estimators of the slope and Y intercept.

The approach of Kim *et al.* [8] is illustrated in Figure 1 with Shewhart charts applied to the data shown in Figure 2. These charts show that the fitted line corresponding to sample four was significantly different from the standard line.

Figure 1 Plot of illustrative phase II calibration data with fitted lines [Reproduced with permission from Gupta *et al.* [9]]

Phase I Methods

Kim *et al.* [8] recommended the use of separate Shewhart charts for the Y intercept, slope, and the error variance in phase I applications provided one codes the X values so that the average X value is zero.

Mahmoud and Woodall [10] proposed a phase I method based on the standard approach of testing collinearity using indicator variables for each profile in a multiple regression model. The performance of several methods was compared for different numbers of shifts of a specified size in the regression parameters. The authors showed that some previously proposed phase I methods are ineffective in detecting shifts in the process parameters due to the ways in which the vectors of estimators were pooled to estimate the variance-covariance matrix. Mahmoud and Woodall [10] illustrated several of the phase I

methods using a calibration dataset given by Mestek *et al.* [5].

Change-point methods (*see Change-Point Methods*) can also be very useful in phase I if one suspects that instability can be modeled adequately by step shifts in the underlying parameter(s). Mahmoud *et al.* [11] developed such a change-point method for the simple linear profile application.

Linear Calibration Applications

As discussed by Kim *et al.* [8], once the parameters are established in a baseline linear calibration study, one would want to detect any change in the Y intercept or slope and any increase in the variation about the regression line since such shifts could correspond to greater inaccuracies in the measurement process. The effect of assignable causes in general, however,

Figure 2 Shewhart control charts using the methods of Kim *et al.* [8] showing a significant deviation from the standard line at sample four [Reproduced with permission from Gupta *et al.* [9]]

will vary from application to application. Sometimes, for example, one may wish to detect isolated outliers.

Croarkin and Varner [12] and ISO 5725-6 [13] recommended a method for monitoring a linear calibration line based on the measurement of three standards at each time period. These are at low, medium, and high values, respectively. The three deviations of the measured values from these standards are plotted simultaneously for each sample on a Shewhart-type control chart. Gupta *et al.* [9] showed, however, that the use of control charts based on the estimated regression parameters is more effective. This latter approach is more interpretable, particularly as the number of standards measured at each time period increases. The NIST/SEMATECH *e-Handbook of Statistical Methods*, available online at <http://www.itl.nist.gov/div898/handbook/>, contains a discussion of the methods proposed by Croarkin and Varner [12].

Other Profile Models and Approaches

As a natural extension of the simple linear regression model, one can consider using control charts to monitor profiles that can be represented by a polynomial regression model or some other multiple linear regression relationship. Jensen *et al.* [14] considered phase II methods for this situation.

In some cases a nonlinear regression model is useful for modeling a profile. A nonlinear model can be used with the vertical board density profile data provided by Walker and Wright [15], where the density of particleboard measured across the diameter of the board is U shaped.

Young *et al.* [16] also considered a vertical density profile application. In their approach, however, the data for each profile were summarized into a top-face, bottom-face, and core average density. Then, a T^2 approach was used for the resulting three-dimensional quality vectors. In general it can be useful to break

the range of the X variable into intervals and to model the profile within each interval. Each “subprofile” could be monitored separately or a T^2 method could be used. This approach seems most promising when assignable causes tend to affect the profile only within certain intervals. It is closely related to the use of wavelet models based on the Haar transform.

Jin and Shi [17] used wavelets to model stamping tonnage signals, profiles which can have a rather complicated shape. They recommended Shewhart charts to monitor changes in wavelet coefficients. In some cases a wavelet coefficient can be associated with a specific process fault. Some additional work was reported by Jin and Shi [2], Lada *et al.* [18], and Zhou *et al.* [3].

Nonparametric, or smoothing, methods do not require a specified functional form for the profile. In nonparametric regression methods, one obtains a smoothed curve that can be expressed as a weighted average of the observed responses. Winistorfer *et al.* [19] used this approach to model vertical density profile data for pressed wood panels.

In a semiconductor application, Gardner *et al.* [4] modeled the spatial signatures (i.e., profiles) of wafers using splines and then used various metrics to compare the profiles of new wafers to an established baseline surface. The metrics used were designed to detect specific equipment faults.

Boeing [20, pp. 140–144] also proposed phase II control charting methods using spline fitting. In their application there were multiple gap measurements made at several locations on a manufactured part. Splines were fit to the responses for each part. The average spline value for the first k splines observed or nominal values are used as the baseline. Metrics such as the maximum difference or the average absolute difference was calculated for each spline relative to the baseline. Individuals X charts and moving range charts are then based on the values of the metrics.

Control Charts, Selection of

Introduction

Control chart selection is the process of matching an appropriate **control chart** with a given application. Successful process monitoring requires several key decisions. Some of these decisions are driven by strategic plans for quality improvement. Examples include the choice of improvement projects, key processes relevant to the project, and **data collection** strategies, such as when and where samples are obtained. Quality leaders must decide on proper actions in response to control chart signals. In this article we only consider the problem of selecting an appropriate type of control chart for a given application. The guidelines provided in subsequent sections are intended to be guiding principles and

not hard and fast rules to which one must adhere. Even experts in the quality area may disagree on final choices of monitoring schemes. There are common themes upon which most experts will agree and these are the focus in the following sections.

Consider the Data

The logic for selecting control charts is similar to general guidelines used in selecting statistical techniques. An appropriate choice among statistical tools depends on the question one needs to answer and the data available to the decision maker. For **quality control** applications, the typical questions of interest concern changes in the mean and/or variance of key process characteristics. For example, we may wish to ensure that produced items are of the correct length on average, and are consistently near target values.

One must investigate several questions concerning the data prior to selecting the type of control chart. These questions include:

Figure 1 Guidelines for control chart selection

Figure 2 Monitoring tools for multivariable environments ^(a)See **Regression Control Charts** ^(b)See **Profile Monitoring** ^(c)See **Neural Networks: Construction and Evaluation** ^(d)See **Change-Point Methods** ^(e)See **Hotelling's T^2 Chart; Multivariate Charts for Variability; Multivariate Control Charts, Interpretation of** ^(f)See **Multivariate Exponentially Weighted Moving Average (MEWMA) Control Chart** ^(g)See **Multivariate Cumulative Sum (CUSUM) Chart**

1. What type of data is available?
2. How much data is available?
3. Are data associated with long production runs or some other process environment such as **batch processes** or short production runs?
4. Is a single-quality characteristic (univariate process control) or multiple quality characteristics (multivariate process control) being considered?
5. If multiple quality characteristics are important, are data values for the various key quality characteristics correlated with one another?
6. Are data values for a given quality characteristic correlated over time (autocorrelated)?
7. What are the distributional properties of the population as reflected by the data? Are common probability distributions, such as the normal, binomial or Poisson distributions useful approximations?
8. Are key output quality characteristics driven by key process input variables? If so, do we have data on both inputs and outputs?

Important questions concerning the process and goals of the monitoring scheme too exist. Depending on the capability of a process, one must determine the size of a shift deemed important enough to detect quickly. Tools for short production runs or batch processes will differ from tools appropriate for long production runs. Unusual or extreme economic consequences associated with process shifts should be noted.

Types of Data

Variables for which data are collected should reflect the current state of a given process quality characteristic. Variables can typically be classified as either quantitative (continuous) or attribute (qualitative, categorical) variables. Quantitative measurements, sometimes referred to as *variables data*, assume values over some continuum, such as length, width, weight, or time. Hence, quantitative variables are associated with continuous probability distributions such as the **normal distribution** or

Figure 3 Monitoring schemes for autocorrelated data, short production runs, or batch data ^(a)See **Control Charts for Short Production Runs** ^(b)See **Control Charts for Batch Processes** ^(c)See **Engineering Process Control; Feedback Control** ^(d)See **Large Autoregressive Integrated Moving Average (ARIMA) Modeling** ^(e)See **Autocorrelated Data**

exponential distribution when appropriate. Attribute data reflect more general properties of process output (e.g., number of surface defects or the classification of items as conforming *versus* nonconforming items). Proportions of nonconforming items found in a sample or counts of defects observed over a given time or space are associated with discrete probability distributions, such as the binomial or Poisson distribution, when appropriate. The distinction between variables with continuous or discrete distributions can become blurred. Time is generally associated with a continuous distribution; however, we report our ages as values truncated to integer values giving discrete data values.

Control charts are often designed for a specific type of data and an associated probability distribution. When these distributions are reasonable, control chart performance is predictable. Control charts associated with specific distributional assumptions can provide quite unexpected performances when

these assumptions are violated. In such cases, one might choose monitoring schemes that are robust to the given assumptions such as nonparametric methods.

Amount of Data

The size of samples as well as the sampling frequency influences the amount of data that one encounters. Additionally, the number of variables required to characterize a process impacts the amount of data one must process. Tools associated with relatively large but infrequent samples for monitoring a single process variable may be inappropriate for small samples or infeasible for automated data collection environments with near continuous data collection on several variables.

Univariate versus Multivariate Environments

One might argue that we always collect data over time, so we always have at least two variables of

Figure 4 Control charts for attribute data ^(a)See **Control Charts for Attributes** ^(b)See **Exponentially Weighted Moving Average (EWMA) Control Chart** ^(c)See **Cumulative Sum (CUSUM) Chart** ^(d)See **Control Charts, Nonparametric**

interest (the quality characteristic and time). Univariate methods are designed to monitor a single-quality characteristic over time. One must address the issue of **autocorrelation** when using univariate monitoring schemes. If values of a variable are correlated over time, special tools are available for exploiting or at least accounting for this source of variation in the process. If the values are not correlated over time, then the added effort and complexity are not worth the gain in information. Simpler tools will be just as informative.

In other cases, one must process data on multiple related variables in a process. Multivariate methods are designed to monitor multiple variables associated with process output characteristics. If these variables are correlated in a quantifiable manner, specialized tools that exploit the **correlation** are appropriate. If the variables are statistically unrelated, multiple univariate methods may be simpler and efficient to use.

Finally, one can encounter situations involving multiple variables, some of which are process output variables and some are process input (driver, explanatory) variables. Understanding the types of data and relationship among the variables allows the

use of specialized tools such as **profile monitoring** or regression-based monitoring schemes.

Guidelines for Control Chart Selection

This section contains several figures helpful in narrowing the appropriate choices of process monitoring schemes. Figure 1 provides our starting point and guidance to subsequent figures and data considerations. For many situations the practitioner has multiple options that are reasonable monitoring schemes. Other articles within this encyclopedia provide specific strengths and weaknesses of each approach and allow the reader to make final selections of tools.

Figure 2 contains the options available to practitioners who must monitor multivariable data. Multivariable data include the case of multiple correlated quality characteristics (multivariate data) and the case of quality characteristics and their associated explanatory variables.

Figure 3 contains the options appropriate for autocorrelated data, short production runs, and batch processes. For autocorrelated data from long production runs, one must determine if automatic process adjustment is a possibility. If so, the techniques associated

Figure 5 Control charts for variables data (univariate) ^(a)See **Control Charts for the Mean; Moving Range and R Charts** ^(b)See **Control Charts for the Mean; Control Charts for the Standard Deviation** ^(c)See **Exponentially Weighted Moving Average (EWMA) Control Chart** ^(d)See **Cumulative Sum (CUSUM) Chart** ^(e)See **Control Charts, Nonparametric** ^(f)See **Change-Point Methods**

with engineering process control (see **Engineering Process Control**) may be more appropriate than traditional statistical process control (see **Control Charts, Overview**).

Figure 4 contains options for attribute data. The most common types of attribute data are proportions of nonconforming items (associated with the binomial distribution) and counts of defects (associated with the Poisson distribution).

Figure 5 contains options for variables data. The appropriate choice among techniques is often driven by normality assumptions or large sample sizes. For small samples which are not approximately normal, robust monitoring techniques are required.

Figure 6 contains some of the options available to practitioners in special situations. These situations include environments where none of the prior figures is appropriate, economic considerations are an overriding concern in control chart development, or control schemes must be built on specification limits.

Although the figures above capture the great majority of cases encountered in practice, they are not all-inclusive. There are some situations which do not fall precisely into any of the environments described above, and similarly, there are good monitoring schemes that are not included in any of the figures. However, practitioners will find the foregoing guidelines a starting point for further investigation, and for the study of process monitoring tools.

Conclusions

The selection of appropriate monitoring schemes requires an understanding of process behavior and basic concepts underlying data and statistics. Control charts range from simple yet powerful statistical tools to quite sophisticated technical monitoring systems. Choosing an appropriate monitoring scheme among many can seem like a complicated process. In some circumstances, the selection process can indeed

Figure 6 Control charts for special circumstances ^(a)See **Economic Design of Control Charts** ^(b)See **Precontrol** ^(c)See **Control Charts, Nonparametric** ^(d)See **Change-Point Methods**

be challenging. Practitioners who find the process difficult should know that statistical assistance is generally available through a number of sources (including, in North America, local chapters of the American Society for Quality (ASQ) and the American Statistical Association (ASA)). Finally, one should find comfort in the knowledge that suboptimal (but reasonable) monitoring schemes applied to good process data is typically far, far superior to no monitoring scheme at all.

Engineering Process Control

Introduction

Engineering **process control** (EPC) (*see Feedback Control*) and **statistical process control** (SPC) (*see Control Charts, Overview*) are techniques for reducing process variation while maintaining target values during production. While both techniques share similar goals, the strategic and mathematical foundations for the two methods are quite different. The goal of this article is to delineate the two methods and provide guidance for their appropriate use.

EPC reduces variation by quantifying process deviations from target. Target values are maintained by process adjustments to compensate for deviations from target values. Underlying this approach is the ability to estimate process levels (current and future) and the existence of an adjustment variable to “control” the process level. The primary focus is reduction of variability by compensating for process shifts. Minimal attention is given to identification and removal of the source cause of the shifts. Process adjustments are typically automated and driven by process measurement rather than operator intervention.

SPC reduces variation by estimating process levels, also. The primary objective is to determine whether the deviations from target values result from common cause variation inherent in the production process, or from special cause variation such as process shifts or malfunctions. Special cause variation results from assignable causes that may be identified and removed. This identification and removal of special causes of variation lead to long-term reduction in process variation and improved process stability. The primary focus is reduction of variation through greater process understanding and “control”. Process adjustments are not typically automated, but require operator investigation and intervention.

The brief descriptions above suggest that EPC and SPC are complementary rather than alternative techniques. The approaches can be combined with good results. Consider the problem of maintaining the temperature of a room at a target value on a summer day. The typical air conditioner exhibits the character of EPC. The room temperature is monitored

(electronically or mechanically) and adjustments are made accordingly. If the temperature is too high, the air conditioner turns on. When the temperature drops too far below target levels, the air conditioner turns off. The inherent drift in temperatures from the coolest to the hottest part of the day is minimized by automatic adjustments by the air conditioning unit. Suppose a window or door in the room were opened and inadvertently left open. The air conditioner would simply continue to run in an effort to compensate for the temperature increase. The air conditioning unit itself would not typically signal that a special cause source of variation (the open door or window) potentially exists. SPC might be used in conjunction with the EPC controller to identify special causes of variation, unaccounted for by EPC. One might monitor the rate or length of EPC activity to identify and intervene in special cause situation such as the open door or window. This example is a gross simplification of most EPC applications, but illustrates the idea of combining EPC and SPC. The combination of EPC and SPC is sometimes called *algorithmic SPC*. Strengths and weaknesses of EPC and SPC are provided in the subsequent sections.

Engineering Process Control – The PID Controller

Proportional–integral–derivative (PID) control is an EPC tool which reduces process variability by adjusting some measurable process variables based on process feedback and compensation. PID control is named after its three terms: proportional, integral, and derivative. Each of the terms performs a different task and has a different effect on the process output. The proportional term responds to the immediate error, but cannot guarantee achieving the target value. In other words, the proportional term can reduce the difference between the output and the target value, but it cannot eliminate the steady state error. The integral term accounts for eliminating the steady state error and it also erases disturbances. However, the integral term does decrease the process stability since it adds up all past errors. The derivative term predicts the future process behavior, and therefore can stabilize the process. A PI controller is also widely used in situations where a derivative term is not needed. The most used form of PID is the parallel form, where the P, I and D terms are made parallelized with each

other and given the same error input. The output is often expressed in the ideal form:

$$\text{Output} = K_p e(t) + K_i \int_0^t e(\tau) d\tau + K_d \frac{de}{dt} \quad (1)$$

where $e(t)$ is the error signal, which is the difference between the target value and the measured output. The values K_p , K_i , and K_d are constants used to “tune” the PID controller. The application of PID has grown tremendously since the invention of PID control in 1910 and the Ziegler–Nichols (Z–N) tuning rule in 1942 [1]. Today, the research and development of PID control focuses on getting the best out of PID [2] and finding the next key technology or methodology for PID tuning [3]. A complete list of PID tuning patents since 1971 can be found in an article by Li *et al.* [4]. O’Dwyer compiles 245 tuning rules in his book, *Handbook of PI and PID controller tuning Rules*, among which 104 are for PI controllers and 141 are for PID controllers. The choice of tuning rules depends on the process type, the parameters, the uncertainties, and so on [5]. For a system that can be taken offline for tuning, the input is increased in a small step, and the output is measured as a function of time, then control parameters are calculated [6]. For a system that cannot be taken offline for tuning, the Z–N type of tuning can be used, in which the controller settings are expressed explicitly in terms of ultimate gain and ultimate period [5]. Modern industrial process largely relies on tuning optimization software to ensure consistent results.

Strengths of EPC

EPC techniques have a number of strengths. Knowledge of EPC behavior and the available research in the area is quite rich. The application of EPC methods has a long and successful history across a wide range of industries.

EPC techniques are especially well suited for situations where process levels drift over time. Such processes produce auto-correlated data (see **Time Series Analysis**). It is worth noting that monitoring auto-correlated data (see **Autocorrelated Data**) is a particularly challenging problem for SPC practitioners. For auto-correlated processes PID control compensates and regulates the process variability

automatically by adjusting measurable variables. PID assumes (a) the next observation is predictable in the process, (b) there are variables that we can manipulate in order to affect the process, and (c) the effect of this manipulated variable can be estimated so that we can determine how much control action to apply [7]. When these conditions are met, PID control can be very effective. In these situations, EPC is more suitable than traditional SPC methods. Process deviation can be compensated by adjusting other known variables, and consequently, the process output can be kept close to the target values by a series of adjustments to these variables [7].

Weaknesses of EPC

PID control does exhibit some limitations relative to SPC. One disadvantage of PID control is that it works only with measurable variables. As mentioned above, PID control adjusts some measurable variables based on feedback in order to compensate the output deviation and keep the output close to its target value. However, there are situations where the inspected item is either classified as “defective” or “nondefective” and quality characteristics are not represented numerically. For example, a sensor used in a computer system is either functional or nonfunctional. Quality characteristics of this type are called *attributes* (see **Control Charts for Attributes**). PID has no ability to control this type of quality characteristics. SPC, on the other hand, can be used under these circumstances by implementing **control chart** for fraction nonconforming (p chart), control chart for nonconformities (c chart), or control chart for nonconformities per unit (u chart).

The implementation of PID largely relies on PID tuning which decides the constants used in the P, I, and D terms to model the process. The PID tuning eventually determines how well PID controllers adjust the process. In practice, many PID controllers do not tune to their optimal parameters. Seborg *et al.* reported that 30% of PID controllers in the pulp and paper industry gave poor performance due to poor tuning [8]. Another common PID problem is “integral windup”. The windup is due to the controller states becoming inconsistent with the saturated control signal, and as a result, future correction being ignored [9]. This might be fixed by introducing a more aggressive differential term or disabling the

integral term until measured variables have entered the proportional band [6]. There are also large problems associated with the derivative term [9]. One of the common derivative term problems is that small amounts of noise can cause large amounts of change in the output. Setting up the derivative term is so complicated that 80% of PID controllers have this term switched off, or omitted completely [2].

Many PIDs control a valve or similar mechanical device. Wear of the valve or device can be a major reason of poor PID performance and increased maintenance costs. Seborg *et al.* reported that 20% of PID controllers in the pulp and paper industry gave poor performance owing to valve problems [8]; Martin reported that half of the valves in the chemical process industry needed to be fixed [10]. Finding diagnostic tools to identify potential valve problems is still at its early stage [11–14]. It is almost impossible to restore all valves to their expected performance, and efforts may involve a large amount of money.

The failure or misperformance of PID usually has severe consequences. The PID controller actually affects final products as it adjusts measurable variables in order to change the output. If there is anything wrong with the PID controller itself, either mistuning, valve problems as mentioned above, or any nonfunctional parts in PID, it may continuously produce defective products until they are recovered by either product inspectors (if there are any) or final users. In the later case, returns or after sale service might be expected and demand extra company resources.

For a more extreme example, consider the case of a motorist using automatic cruise control. The failure or misperformance of a cruise control system, which is a PID controller, might put the person behind the wheel in danger. Hydroplaning is a well-known phenomenon. In rain, a layer of water builds up beneath tires. As you drive at a high speed, the car begins sliding on this layer, and tires lose contact with the road sometimes. If a cruise control system is activated, it will try to spin the tires faster to compensate the reduction in speed. The driver may lose control when tires contact the road again. An accident happens as a consequence.

The ability of EPC and SPC to handle the false alarms also differs. False alarms occur because the process variability cannot be totally eliminated. For single unusual measurements associated with no process abnormality, PID control will respond to this

false alarm and adjust its current correct settings to incorrect settings based on false information. Consequently, defective products may be produced. PID control does have the ability to correct this error over time. However, defective products have already been produced.

PID control automatically adjusts to keep the process on target. No action is taken to identify assignable causes in the process. One is unable to determine if there is a problem in the production line, such as poor operation, raw material problems, and so on. On the other hand, SPC can alert management when there are problems in the process. The control charts will have out of control data, which warns the management that there are problems in the process and corresponding actions need to be taken to correct the problems.

Conclusions

The choice between EPC and SPC methods is driven by the characteristics of the production process and the goals of the practitioner. EPC methods are especially well suited for stable processes whose mean levels tend to drift in a predictable manner and for which automatic measurement and adjustment is possible. SPC methods are more appropriate for environments where automated control is not feasible, or when assignable causes of process shifts must be identified and eliminated. While the approaches of EPC and SPC have been viewed as competing philosophies and methodologies, one may reasonably view them as complementary tools. The strengths of one approach complement the weaknesses of the other.

As a final note, using EPC and SPC in combination is a particularly powerful option. The simultaneous use of these methods is sometimes called *algorithmic SPC*. The interested reader may find more information in Wander Weil *et al.* [15].

Feedback Control

Introduction

A process is a transformation between an input and an output (Figure 1). Engineering **process control** (EPC) is a discipline that deals with controlling the output of a specific process; the goal of which is to reduce variability in a key variable at the output of a process. For example, maintaining the temperature in a room is a process that has the specific outcome to reach a defined temperature and keep it constant over time. In Figure 2, the temperature is the controlled or output variable. At the same time, it is an input or variable since it is measured by a thermometer and used to decide whether to heat or not to heat. The desired temperature is the target or set point. The state of the heater (e.g., the setting of the valve allowing hot water to flow through it) is called the *manipulated variable* since it is subject to control actions. The controller makes adjustments to the variable so that the process stays on target.

Figure 1 represents the simplest, but unlikely structure for the input and output variables. Typically, there is noise in the system as Figure 3 demonstrates. Figure 3 also shows a dynamic system. In a dynamic process, the characterization of a relationship that

Figure 1 A basic process model

Figure 2 A controlled process

links the input to the output is more difficult than in a steady-state process. A change to a dynamic process may take several time periods to be fully realized, whereas a change to a steady-state process is observed in the next time period.

Dynamic behavior occurs when the output, Y_t , of a process does not respond instantaneously to a change in the manipulated input, U_t . The modeling problem becomes more challenging with the presence of a noise process that affects the output. Noise may occur anywhere in the system; the complete effect of the noise is measured at the output and hence represented as affecting the output. The noise process, y_t , is modeled as a series of random shocks, u_t , that pass through a linear filter. Figure 3 also shows that a controller uses the information available at the output, that is, the sum effect of y_t and Y_t to adjust the process. This type of model has been widely used to represent dynamic industrial processes that are sampled over time [1–3].

Control Strategies

There are many control strategies or algorithms that the controller may use. A control strategy is where a variable(s) is measured and the measurement is used to adjust another process variable which can be manipulated. A more common name for this activity is EPC. A typical control objective is to minimize the variance of the output deviations from a target (or set point) or minimum mean square error (MMSE) control. A criterion in developing an adjustment policy under this objective is cost. If the cost of a process adjustment is zero, then an adjustment is made at every sampling interval. If the cost of adjustment is nonzero, then an adjustment is made only if a significant deviation from the target occurs.

Consider a process in which the output at a specific period of time is Y_t and the process target is T . The goal of proportional-integral-derivative (PID) control is to keep the process output Y_t close to the target T . By adjusting a controllable or manipulative variable the error term, $e_t = T - U_t$, is kept close to zero. There are different methods available in literature, but the most common ones are proportional control, integral control, derivative control, and a combination of these three also known as *proportional-integral-derivative controller*. In EPC, PID controllers are a standard [4, 5].

2 Feedback Control

Figure 3 A general model of a process, noise process, and controller

Proportional Control

Proportional control adjusts the controllable variable by a certain proportion called the *gain*: $Y_t = K_p e_t$, where the constant K_p is the proportional gain. The larger the error or offset is, the larger K_p is to bring the process near the target. The drawback to proportional control is that the system may never achieve steady state: the system either oscillates back and forth around the set point because there is nothing to remove the error when it overshoots, or oscillates and/or stabilizes at a too low or too high value.

Integral Control

Integral control sums the current and previous errors over a period of time and added to the manipulated variable: $Y_t = K_i \int_0^t e_t dt$ where the constant K_i is the integral gain. By appropriately selecting an integral control gain term, the steady-state error can be reduced significantly. However, the system may become unstable and produce an overshooting or undershooting effect.

Derivative Control

Derivative control provides a control proportional to the rate at which a process output is deviating with

respect to its previous output: $Y_t = K_d de/dt$ where the constant K_d is the derivative gain. The response to a system change largely depends on the magnitude of K_d : the larger the term, the more quickly the controller responds. One of the main advantages of using derivative control is the minimization of the overshooting or undershooting effect by using information about the rate of change of process output. However, the transient response time is increased by selecting a high value of K_d .

PIDControl

The PID controller combines the above control strategies for control over steady-state and transient errors: $Y_t = K_p \left(e_t + K_i/K_p \int_0^t e_t dt + K_d/K_p de/dt \right)$.

It provides a mechanism to bring an automatic process to target by providing feedback adjustments. It is a very robust tool for process adjustments and enjoys a high esteem in the process control literature. These control strategies may also be combined to form PI and PD controllers. In process control applications, PI control (which is also the exponentially weighted moving average **EWMA**) is responsible for more than 95% of the system control loops. Although these tools are common for making adjustments to

a process, they are usually designed for steady-state behavior [1, 6, 7].

EPC/SPC Integration

There has been a significant amount of discussion in the literature on the difference of statistical process control (SPC) and EPC in terms of their applications context. Traditional SPC emphasizes that any observed difference between a controlled process variable and its desired value may be due to inherent common cause variation (thus no system change is necessary) or systematic special cause variation (where a system change may be necessary). The goal of SPC is to monitor the process so that there is a good chance of detecting the special cause so that it can be removed. The underlying assumption is that there is a disincentive to make an adjustment after every observation period because they are costly. On the other hand, traditional EPC assumes that the process input variables can be adjusted as frequently as desired, that the adjustments are virtually cost free, and that the process output variables can be measured on line without any associated uncertainty [8].

Recently, we have seen an increasing research enthusiasm in combining (or integrating) SPC and EPC techniques despite their differences. One benefit of the combination stems from reducing the mean squared error. By integrating basic EPC and SPC policies, it is possible to reduce the output variance in some systems beyond the capabilities of either tool individually [6, 9–13]. Montgomery *et al.* [14] demonstrate this using a modified funnel experiment in combination with an SPC chart monitoring deviation from target. Another benefit is making an adjustment less often. This may be particularly relevant for systems where there is a distinct cost associated with making each adjustment or where the adjustment must be manually imposed by an operator.

Integrating EPC and SPC has applications to startup periods [15, 16], to run-to-run control [17, 18], and to multivariable control [19, 20] to name just a few.

Change-Point Methods

Introduction

Statistical process control (SPC) methods are intended to detect departures from an in-control state, which are the result of special cause variability. Two broad classes of departures are isolated or intermittent ones, in which the special cause appears and then disappears even in the absence of some corrective action, and sustained or persistent ones that, once introduced, tend to continue until corrective action remedies them. Persistent special causes further subdivide into those that have erratic effects and those that shift the process from its in-control state to a different, stable out-of-control state. These latter special causes provide the motivation for the change-point formulation.

Notation and Approaches

From the statistical viewpoint, the in-control and out-of-control states are distinguished by the distribution of the process measurement stream. Write $X_1, X_2, \dots, X_n, \dots$, for the sequence of readings (which could be uni- or multivariate). A convenient starting point for discussion is that, while in control, the readings are independent and follow some statistical distribution $f(x, \theta)$ with the parameter vector θ having its in-control value θ_0 . Under a persistent change at some time τ , the readings follow this distribution up to time τ , after which their behavior changes to something else. Under the conventional change-point model, this changed behavior has the same distribution with the parameter θ taking the new value θ_1 . If the change point τ were known, we would have a standard two-sample comparison. Sometimes this is the case – we know that something happened at time τ (for example a plant switched suppliers at time τ) and want to test whether it had a visible effect on the process. More commonly, we do not know that changes have intervened until we detect and diagnose their effects. In line with this situation, we will assume τ is unknown.

If both θ_0 and θ_1 are known, then the SPC diagnostic of choice is generally a cumulative sum (**cusum**) chart, with its minimum time to detection

property. The change-point formulation is therefore of interest in settings where at least one of these parameters is unknown. As it is rare for the out-of-control distribution to be known when the in-control one is not, we ignore this possibility, and consider the following situations:

- θ_0 known, θ_1 unknown; and
- both θ_0 and θ_1 unknown.

The approach to testing for a change point is the same; the log-likelihood of the sequence $X_1, \dots, X_n$ under the change-point model is the sum of two terms: one for the in-control and one for the out-of-control portions of the sequence:

$$\log L(\theta_0, \theta_1, \tau) = A(\theta_0, \tau) + B(\theta_1, \tau, n) \quad (1)$$

where $A(\theta_0, \tau) = \sum_{i=1}^{\tau} \log f(X_i, \theta_0)$ is the in-control portion, and $B(\theta_1, \tau, n) = \sum_{i=\tau+1}^n \log f(X_i, \theta_1)$ is the out-of-control one. If any of the parameters are unknown, then they are estimated by maximizing the likelihood. So if, for example θ_1 is unknown, as it commonly is, then it is replaced by the value $\hat{\theta}_1$ maximizing the $B(\theta_1, \tau, n)$ term, and similarly for θ_0 . The change point τ is estimated as the value k maximizing the sum $A(\theta_0, k) + B(\hat{\theta}_1, k, n)$ if θ_0 is known, and $A(\hat{\theta}_0, k) + B(\hat{\theta}_1, k, n)$ if it is not. If there is no change point, then the log-likelihood is $A(\theta_0, n)$. Thus the conventional generalized likelihood ratio (GLR) test for the presence of a change point is $2[\log L(\hat{\theta}_0, \hat{\theta}_1, \hat{\tau}) - A(\hat{\theta}_0, n)]$ if θ_0 is unknown, and $2[\log L(\theta_0, \hat{\theta}_1, \hat{\tau}) - A(\theta_0, n)]$ if it is known.

As with many other likelihood-ratio methods, this test can often be reexpressed in different but functionally equivalent forms.

Normally Distributed Data

The easiest and most familiar example is normally distributed data. Switching to a more standard notation, suppose that the preshift in-control distribution of the data is $N(\mu_0, \sigma_0^2)$ and the postshift out-of-control distribution is $N(\mu_1, \sigma_1^2)$. It is most commonly assumed that the mean changes following the shift, i.e. $\mu_0 \neq \mu_1$. One family of change-point formulations, the homoscedastic models, assumes that $\sigma_0 = \sigma_1 = \sigma$ say, and the other, the heteroscedastic model, allows $\sigma_0 \neq \sigma_1$.

2 Change-Point Methods

Write $\bar{X}_{ik} = \sum_{j=i+1}^k X_j / (k - i)$ for the mean of the sequence $X_{i+1}, \dots, X_k$ and $V_{ik} = \sum_{j=i+1}^k (X_j - \bar{X}_{ik})^2$ for the sum-of-squared deviations of these observations about their mean. Then splitting at a trial value $\tau = k$, gives maximum-likelihood estimators (MLEs) $\hat{\mu}_0 = \bar{X}_{0k}$, $\hat{\mu}_1 = \bar{X}_{kn}$ for the means, and for the unequal variance setting, $\hat{\sigma}_0^2 = V_{0k} / (k - 1)$ and $\hat{\sigma}_1^2 = V_{kn} / (n - k - 1)$ for the separate variances, or in the homoscedastic case, $\hat{\sigma}^2 = (V_{0k} + V_{kn}) / (n - 2)$.

These variance estimators are not, strictly speaking, MLEs, as they have been scaled by their **degrees of freedom**, and not by the sample sizes on which they are based, but this situation is standard.

Homoscedastic Case

In the homoscedastic case, the estimator of the change point τ is the value of k that maximizes, in absolute value,

$$U_{kn} = \sqrt{\frac{k(n-k)}{n}} (\bar{X}_{0k} - \bar{X}_{kn}) \quad (2)$$

or equivalently, minimizing $V_{0k} + V_{kn}$.

Write $U_{\max,n}$ for this maximized absolute value. The test statistic for a change point at an unknown time τ is then $U_{\max,n} / \sigma$ if σ is somehow known, and in the more common situation that it is not known, is $T_{\max,n} = U_{\max,n} / \hat{\sigma}$. This is just the absolute maximum across k of the two-sample t -test comparing the “samples” $X_1, \dots, X_k$ and $X_{k+1}, \dots, X_n$.

The test can also be expressed as the maximum of the F ratio in an analysis of variance comparing these two samples as:

$$\begin{aligned} F_{\max,n} &= \max_k \left[\frac{V_{0n} - V_{0k} - V_{kn}}{V_{0k} + V_{kn}} (n - 2) \right] \\ &= T_{\max,n}^2 \end{aligned} \quad (3)$$

In the setting where μ_0 is already known exactly, U_{kn} is redefined as $U_{kn} = \sqrt{n - k} (\mu_0 - \bar{X}_{kn})$ and there is a corresponding minor adjustment in the pooled standard deviation if σ has to be estimated, but the broad thrust of the procedure is unchanged. See related publications such as [1–4].

Heteroscedastic Case

There are two interesting change-point tests to perform in the heteroscedastic setting. One is to test for a change in the variance without regard to whether the mean changed when the special cause intervened. The other is to test the possibility of a change in the mean, the variance, or both. Likelihood-ratio test (LRT) statistics for these possibilities start out with:

Test variance only [5]:

$$G_{kn} = \frac{\left[(k-1) \log \left(\frac{\hat{\sigma}_0^2}{\hat{\sigma}_1^2} \right) + (n-k-1) \log \left(\frac{\hat{\sigma}_1^2}{\hat{\sigma}_0^2} \right) \right]}{B} \quad (4)$$

with

$$B = 1 + \frac{[(k-1)^{-1} + (n-k-1)^{-1} - (n-2)^{-1}]}{3} \quad (5)$$

Test mean and/or variance shift [4]:

$$G_{kn} = \frac{\left[k \log \left\{ \frac{k V_{0n}}{n V_{0k}} \right\} + (n-k) \log \left\{ \frac{(n-k) V_{0n}}{n V_{kn}} \right\} \right]}{B} \quad (6)$$

with

$$\begin{aligned} B &= 1 + \frac{11}{12} [k^{-1} + (n-k)^{-1} - n^{-1}] \\ &\quad + [k^{-2} + (n-k)^{-2} - n^{-2}] \end{aligned} \quad (7)$$

The constants B are Bartlett correction factors intended to improve the approximation of the distribution of these statistics to χ^2 distributions with degrees of freedom 1 and 2 respectively for fixed k and n . As with the shift-in-mean problem, the unknown time of change τ is estimated by the k value that maximizes the test statistic.

Theoretical Results

For a given k , U_{kn} / σ follows a standard **normal distribution**, and T_{kn} follows a t distribution with $n - 2$ degrees of freedom. Maximization of either statistic over k however takes the distributions out of the realm of these familiar standard distributions. There is a vast literature on the fixed-sample homoscedastic mean change-point problem where the sample size

n is fixed (see for example [6] and [7] where the technical difficulties are discussed in detail). This situation of a fixed sample size is relevant in a quality setting to the analysis of phase I data. Specific applications to SPC are discussed in [8].

Phase II SPC

In phase II SPC, the sample size is not fixed. Rather, while the process is thought to be in control, additional readings are added to the record and incorporated into the **control charts**. As each new reading is obtained, a decision has to be made of whether the process still appears to be in control. If so, then the reading is incorporated into the history and the process is allowed to continue. If, however, the reading gives rise to a suspicion that the process is now out of control, then the process is stopped for diagnosis and remedial action.

Returning to the generic change-point formulation, a purely-change-point-driven procedure can be described as:

- When each new observation accrues, calculate

$$C_n = \max_k 2[\log L(\hat{\theta}_0, \hat{\theta}_1, k) - A(\hat{\theta}_0, n)] \quad (8)$$

- If $C_n < c_n$ then conclude that there is no evidence of a shift.
- If $C_n > c_n$ then conclude that there is evidence of a departure from control.

The sequence c_n is a sequence of control limits chosen to control the false-alarm behavior of the scheme. Finding this sequence c_n does not seem to be amenable to theoretical analysis, and actual implementations of the change-point method have used simulation to find suitable values.

A particular attraction of the change-point method is its postsignal diagnostic capability. Under the model that the process did indeed have a persistent step change from the in-control to the out-of-control parameter value, the k value maximizing the likelihood ratio gives an estimate of τ , the last reading before the shift, and the corresponding $\hat{\theta}_1$ provides a maximum-likelihood estimate of the out-of-control parameter value. Although these estimates maximize likelihood, they do not necessarily have the usual “good” properties of MLEs such as consistency.

The Change-Point Method as Follow-Up

This sketches the use of the change-point method as a self-contained phase II charting methodology. This is not the only way it can be used. For example some other method such as a Shewhart, cusum, or exponentially weighted moving average (EWMA) chart may be used to detect departure from control and following this signal, the change-point calculations may be done in an essentially phase I fashion to estimate the time of the change and the postchange parameters. Relevant articles are [9–11].

In this use, the conventional distributional results of the pure change-point theory are largely inapplicable. Test statistic distributions for example, assume that the data follow some specified (for example common normal) distribution; these distributions do not apply when we condition on the fact that the data look suspicious to some other charting method.

Existing Change-Point Formulations

The change-point framework is general; specific existing applications are as follows:

- normal data, where the mean may undergo a step change [1];
- normal data, where the variance may undergo a step change [5];
- normal data, where the mean and/or variance may undergo a step change [12];
- multivariate normal data, where the mean vector may undergo a step change [13]; and
- regression data, where the dependence of a process variable on some **covariate** may undergo a step change [14].

The framework is however more general than a menu of existing implementations might suggest. There is nothing to prevent, for example the in-control distribution, not one of independent identically distributed readings, but say a **time series**, being modeled by an autoregressive integrated moving average scheme whose coefficients can change when the process goes out of control. This model involves additional computational, but not conceptual, complexity.

Multiple Change Points

The discussion so far has assumed that the process history shows a maximum of one change point. This raises the question of whether attention to multiple change points is needed. There is a case for arguing that it is not – that when the process goes out of control, the process owner should diagnose the situation as soon as the control scheme provides an alert. Following this, the data identified as seeming out of control should be excised from the in-control record, and when charting starts up again, the change-point calculations should be restarted from the last in-control point, and new process readings should be added sequentially.

Comparison with Other Methods

As noted earlier, SPC settings can be divided into those involving transient and persistent special causes. The latter may give rise to either erratic data or some shifted statistical distribution. A further distinction is between settings where the in-control statistical distribution is known exactly (perhaps as a result of an earlier large phase I study) and those in which the in-control parameters are not known exactly.

The standard SPC methods of Shewhart, cusum, and EWMA charting assume that the in-control parameters are known exactly. The more common reality is that they are estimated from finite phase I samples, and recent research has shown that these phase I samples need to be very large if the known-parameter run behavior is to be realistic.

The difficulties caused by these imperfectly known in-control parameters can logically be accommodated in two ways – by adapting the control limits or interpretive rules of the standard charts and by using methodologies that accommodate unknown parameters explicitly. The self-starting approach is an example of the latter, as is the unknown-parameter change-point formulation. They differ in that the self-starting method makes no assumption about the out-of-control distribution of the data, whereas the change-point formulation does. Logically, if the change is persistent and leads to stable behavior, then change-point methods should be the methods of choice; if the change is persistent but leads to erratic behavior, then the unmet assumption of stable behavior should make change-point formulations less effective.

Example: Gold Mine Sampling QC

This example fits the more general scenario where changes in both mean and/or variance are important and can hinder the performance of a process. We refer the reader to [12] for a fuller discussion and details on this example. The objective is to monitor gold mine samplers. Samplers in gold mines chip out rock samples of the “face” where the ore is being extracted and submit them for chemical assay to measure their gold content. As a quality check, supervisors cut out fresh samples at some of the locations already sampled. This gives rise to pairs of samples and of gold content – one by the original sampler and one by the supervisor, an experienced sampler. The log of the ratio of the gold content of the sampler to that of the supervisor has an approximately normal distribution. This distribution should have a zero mean (else the sampler is biased), and a small variance (else the sampler is erratic). Figure 1 shows a sequence of such log ratios for a junior sample.

Change points in both mean and variance are possible and important. A change in mean leads to a bias in mine valuation. An increase in variance may warn of loss of motivation to sample carefully, while a decrease in variance indicates a highly desirable improvement in measuring quality, perhaps as a result of learning skills. We will address these questions using the more general setting of change-point formulation to look for changes in this sampler’s output. Visually, Figure 1 suggests that the variability in the portion up to around observation 40 is higher than that for the remainder of the sequence. The mean, however, appears to center on zero for

Figure 1 Sample versus log ratio of sampler over supervisor

90	-0.052	0.283	28.79	1.06	-0.53	5.22	-7.15

the whole sequence. Figure 2 gives the chart of the GLR along with the control limit $c_{n,0.002}$, where $c_{n,0.002}$ is chosen to yield an in-control average run length (ARL) of 500 for normal data. The chart first crosses the control limit at reading 70, and continues upward except for a brief dip below at reading 74. Right from the first hint of a change point, the GLR gives the left-segment estimates $\hat{\tau} = 42$, $\hat{\mu}_1 =$

0.053, $\hat{\sigma}_1 = 0.42$. Table 1 lists the summary statistics of the right segment parameters, the GLR, the t -, and the F -test statistics for identity of mean and of variance, and the base-10 log of their normal-distribution p values. These confirm that there is no indication of a shift in mean, but that the standard deviation is substantially smaller after the change point than before. By the time of the first signal at sample number 70, the estimated postchange standard deviation has stabilized close to its ultimate value of 0.283 – about two-thirds of its value in the first portion of the series. This reduction of variance is of substantial value to the mine. It means that each sample now produced by this junior sampler is more informative than two of his previous samples were. This has obvious implications for the improvement in mine valuation and selection of which ore to extract.

Autoregressive Integrated Moving Average (ARIMA) Modeling

Introduction

A time series is the result of observing a magnitude over time (*see Time Series Analysis*). For instance, one can observe the number of defects in a production process every day, the thickness of a coating layer every hour, or the monthly demand for a product. An important class of time series is the stationary one. A time series is stationary if it is stable over time, so that the level of the series is constant, the variability is also constant, and the dependency relationships between successive values of the time series do not change over time.

Many real time series are not stationary but can be transformed to stationarity. Thus a nonstationary series $\{y_t\}$ that wanders over time without a fixed mean may have the property that its growth $x_t := y_t - y_{t-1}$ is a stationary time series. Then we say that the series $\{y_t\}$ is *integrated* and that the series $\{x_t\}$ is the *first difference* of $\{y_t\}$.

ARMA (auto-regressive moving average) models are useful to approximate the dynamics of many stationary time series, whereas ARIMA (autoregressive integrated moving average) models are useful for integrated time series. Figure 1 shows three time series generated by simulation using two ARMA models (a and b) and one ARIMA model (c). Simple inspection of these series shows that they have different dynamics because of their different autocorrelation structures (*see Autocorrelated Data*). The general form of ARMA and ARIMA models will be considered subsequently.

ARMA Models

A process $\{y_t\}$ is called stationary in the weak form if $E(y_t)$ and $\gamma_k := \text{cov}(y_t, y_{t+k})$ for $k = 0, 1, \dots$ are finite and do not depend on t . The sequence $\{\gamma_k\}$ is called the *autocovariance function* and $\rho_k := \gamma_k/\gamma_0$ is the *autocorrelation function* (*see Autocorrelation Function*). Wold [1] proved that any stationary process, $\{y_t\}$, without deterministic components can

be written as

$$\begin{aligned} y_t &= a_t + \psi_1 a_{t-1} + \psi_2 a_{t-2} + \dots \\ &= \sum_{i=0}^{\infty} \psi_i a_{t-i} \quad (\psi_0 = 1) \end{aligned} \quad (1)$$

where $\sum_{i=0}^{\infty} \psi_i^2 < \infty$ (*stationarity condition*) and $\{a_t\}$ is a zero-mean white noise process ($E(a_t a_{t+k}) = 0$ for $k \neq 0$) with variance $\sigma^2 := E(a_t^2)$. This is called the general, or the infinite **moving average** MA(∞), representation of a stationary process. Model (1) leads to $E(y_t) = 0$. If the process $\{y_t\}$ has deterministic mean $\{\mu_t\}$, the general representation applies to the zero-mean process $\{y_t - \mu_t\}$. The autocovariance function is $\gamma_k = E(y_t y_{t+k}) = \sigma^2 \sum_{i=0}^{\infty} \psi_i \psi_{i+k}$, for $k \geq 0$ (see also Appendix 1). Using the lag operator B such that $B y_t = y_{t-1}$, the MA(∞) representation can formally be written as $y_t = \psi(B) a_t$, where $\psi(B) = 1 + \psi_1 B + \psi_2 B^2 + \dots$. The white noise $\{a_t\}$ can often be assumed to be normally distributed.

If model (1) is invertible, it can be written in an alternative way that is called the infinite autoregressive AR(∞) representation of the process and is given by

$$y_t - \pi_1 y_{t-1} - \pi_2 y_{t-2} - \dots = y_t - \sum_{i=1}^{\infty} \pi_i y_{t-i} = a_t \quad (2)$$

where $\sum_{i=1}^{\infty} \pi_i^2 < \infty$ (*invertibility condition*). Model (2) can formally be written as $\pi(B) y_t = a_t$, where $\pi(B) = 1 - \pi_1 B - \pi_2 B^2 - \dots$, so that $\pi(B) \psi(B) = 1$.

These two general representations have an infinite number of parameters. Approximations having a finite number of parameters are needed to model any finite time series $\mathbf{Y}' = (y_1, \dots, y_n)$. The simplest approximation is to assume a finite number q of terms in equation (1), which leads to the q -order moving average MA(q) model $y_t = \theta_q(B) a_t$, where $\theta_q(B) = 1 - \theta_1 B - \dots - \theta_q B^q$ (minus signs are used customarily). For MA(q) models, $\gamma_0 = \sigma^2(1 + \theta_1^2 + \dots + \theta_q^2) < \infty$, so that they are always stationary; moreover $\rho_k = 0$ for $k > q$. A second way to approximate the general form is to use a finite number p of terms in equation (2). This leads to the p -order autoregressive AR(p) model $\phi_p(B) y_t = a_t$, where $\phi_p(B) = 1 - \phi_1 B - \dots - \phi_p B^p$. An AR(p) model is *stationary* if and only if all the roots of

Figure 1 Time series generated using the AR(1) model $y_t - 0.8y_{t-1} = a_t$ (a), the MA(1) model $y_t = a_t - 0.8a_{t-1}$ (b), and the IMA(0, 1, 1) model $y_t - y_{t-1} = a_t - 0.2a_{t-1}$ (c), for a common simulated white noise series $(a_1, \dots, a_{200})$ with zero mean and variance $\sigma^2 = 1$

the polynomial $\phi_p(B)$ are outside the unit circle, so that the model accepts the MA(∞) representation $y_t = \phi_p^{-1}(B)a_t$. Thus the AR(1) model $(1 - \phi B)y_t = a_t$ can be written as $y_t = (1 - \phi B)^{-1}a_t = (1 + \phi B + \phi^2 B^2 + \dots)a_t$ if and only if $|\phi| < 1$, so that $\gamma_0 = \sigma^2(1 - \phi^2)^{-1} < \infty$; the autocorrelation function is $\rho_k = \phi^k$ implying a geometrical decay of $\rho_k \neq 0$, which is a feature common to all stationary AR(p) models.

The AR(p) and MA(q) models can be combined to form the ARMA(p, q) model $\phi_p(B)y_t = \theta_q(B)a_t$. ARMA(p, q) models are *stationary* if and only if all the roots of $\phi_p(B)$ are outside the unit circle, and they are *invertible* if and only if all the roots of $\theta_q(B)$ are outside the unit circle. Only invertible models yield time series *forecasts* directly (see the section titled “Forecasting Time Series”).

ARIMA Models

ARMA(p, q) models can be extended to model the dynamics of integrated time series. A nonstationary

process $\{y_t\}$ whose d th difference $\{(1 - B)^d y_t\}$ is stationary is called an *integrated* process of order $d > 0$. Using the operator $\nabla = 1 - B$, the general ARIMA(p, d, q) equation is

$$\phi_p(B)\nabla^d(y_t - \mu_t) = \theta_q(B)a_t \quad (3)$$

where $\phi_p(B)$ and $\theta_q(B)$ have no common roots and are invertible (i.e., all their roots are outside the unit circle), and $\{\mu_t\}$ is a deterministic trend. In model (3), $\{\nabla^d \mu_t\}$ is the mean of the differenced series $\{\nabla^d y_t\}$ and is estimable, but the d integrating constants in $\{\mu_t\}$ cannot be estimated. Important examples of this type of models are the random walk, $y_t = y_{t-1} + a_t$, also called ARIMA(0, 1, 0) or I(1), and the IMA(0, 1, 1) model $y_t = y_{t-1} + a_t - \theta a_{t-1}$.

Under model (3), $\{\nabla^d(y_t - \mu_t)\}$ is a zero-mean stationary process. The mean and variance of y_t conditioned on given past values $\{y_0, y_{-1}, \dots\}$ are finite. Thus for a random walk $y_t = y_{t-1} + a_t$ and $t > 0$, one has $E(y_t|y_0) = y_0$ whereas $\text{var}(y_t|y_0) = \sigma^2 t$ increases indefinitely as t increases. Also, for $k > 0$,

$\text{cov}(y_t, y_{t+k}) = \sigma^2 t \geq 0$, so that the autocorrelation coefficient $\rho(y_t, y_{t+k}) = (1 + k/t)^{-1/2}$ decreases with k , which is a property of integrated processes. The function $V(k) = \frac{1}{2} E(y_k - y_0)^2 = \gamma_0(1 - \rho_k)$ is called the *variogram*. The quotient $V(k)/V(1)$ is called [2] the *standardized variogram* (SV) and is a dimensionless function of k . The SV of ARMA models is $(1 - \rho_k)/(1 - \rho_1)$ and is always bounded. Unlike the autocovariance function, the SV of ARIMA($p, 1, q$) models always exists and equals $k + 2 \sum_{i=1}^{k-1} (k-i) \text{corr}(\nabla y_t, \nabla y_{t-i})$; for the IMA(0, 1, 1) model, it is $1 + (k-1)(1 - \theta)^2/(1 + \theta^2)$ and increases linearly with k .

Applications

ARIMA models are important for generating forecasts and providing understanding in all kinds of time series problems from economics to health care applications [2–9]. In particular, in quality and reliability, they are important in process monitoring if observations are correlated, designing schemes for process adjustment, monitoring a reliability system over time, forecasting time series, estimating missing values, finding **outliers** and atypical events, understanding the effects of changes in a system, and so on.

Forecasting Time Series

ARIMA models can be used to forecast time series. Forecasting with ARIMA models is very simple when $q = 0$. Using the notation $\phi_p(B)\nabla^d = 1 - \varphi_1 B - \dots - \varphi_{p+d} B^{p+d}$ and assuming, for simplicity, that $\mu_t = 0$ in equation (3), the minimum mean squared error (MMSE) forecast of y_t given $(y_{t-1}, \dots, y_{t-p-d})$ is $\hat{y}_t = \varphi_1 y_{t-1} + \dots + \varphi_{p+d} y_{t-p-d}$. The forecast error is a_t . When $q > 0$, however, the forecasts depend on previously observed forecast errors. Thus for given observations $(y_{t-1}, \dots, y_{t-p-d})$, and computed forecast errors $(a_{t-1}, \dots, a_{t-q})$, the MMSE forecast of y_t is

$$\begin{aligned} \hat{y}_t = & \varphi_1 y_{t-1} + \dots + \varphi_{p+d} y_{t-p-d} \\ & - \theta_1 a_{t-1} - \dots - \theta_q a_{t-q} \end{aligned} \quad (4)$$

and the forecast error is a_t . The quick recursion (4) is numerically stable when used iteratively if and only if $\theta_q(B)$ is *invertible*.

For a finite series $\mathbf{Y}' = (y_1, \dots, y_n)$, equation (4) is exact only asymptotically and has to be initialized. Suppose a series $\mathbf{Y}$ having zero mean and **covariance** matrix $\mathbf{\Omega} := \text{cov}(\mathbf{Y})$ has to be forecast. This problem can be formulated as successively finding uncorrelated (orthogonal) forecast errors $\mathbf{E}' = (e_1, \dots, e_n)$ with zero mean and covariance matrix $\mathbf{D} := \text{cov}(\mathbf{E}) = \text{diag}(D_{11}, \dots, D_{nn})$. This can be solved by applying Gram–Schmidt orthogonalization to $\mathbf{Y}$. Then $\hat{\mathbf{Y}} = \mathbf{Y} - \mathbf{E}$. Starting with $e_1 = y_1$ (so that $D_{11} = \Omega_{11}$ and $\hat{y}_1 = 0$) and using $e_t = y_t - \hat{y}_t = y_t - \sum_{j=1}^{t-1} \lambda_{tj} e_j$, one gets $\text{cov}(y_t, e_i) = \text{cov}\left(e_t + \sum_{j=1}^{t-1} \lambda_{tj} e_j, e_i\right) = \lambda_{ti} \text{var}(e_i)$ and $\text{cov}(y_t, e_t) = \text{var}(e_t) = D_{tt}$. Then $\lambda_{ti} = \text{cov}(y_t, e_i)/\text{cov}(y_i, e_i)$. The required covariances are found using the recursion

$$\begin{aligned} \text{cov}(y_t, e_i) &= \text{cov}\left(y_t, y_i - \sum_{j=1}^{i-1} \lambda_{ij} e_j\right) \\ &= \Omega_{ti} - \sum_{j=1}^{i-1} \lambda_{ij} \text{cov}(y_t, e_j) \end{aligned} \quad (5)$$

for $t = 1, \dots, n$ and $i = 1, \dots, t$. Hence $\mathbf{Y} = \mathbf{L}_{\Omega} \mathbf{E}$, where $\mathbf{L}_{\Omega}$ is the lower triangular matrix with elements λ_{tj} for $t = 1, \dots, n$ and $j = 1, \dots, t$ (note that $\lambda_{tt} = 1$), and $\mathbf{\Omega} = \mathbf{L}_{\Omega} \mathbf{D} \mathbf{L}_{\Omega}'$.

If the series $\mathbf{Y}$ is generated by the ARMA(p, q) model $\phi_p(B)(y_t - \mu_t) = \theta_q(B)a_t$, $\mathbf{\Omega}$ has elements $\Omega_{ij} = \gamma_{|i-j|}$. Then, it is advantageous to apply the recursion (5) to the working series $\mathbf{W}' = (w_1, \dots, w_n)$ defined by $w_t = y_t - \mu_t$ for $t = 1, \dots, p$ and $w_t = \phi_p(B)(y_t - \mu_t)$ for $t = p+1, \dots, n$, because $\mathbf{\Omega}$ is replaced by the *band* matrix $\mathbf{\Theta} := \text{cov}(\mathbf{W})$ (see Appendix 2). Then $\mathbf{W} = \mathbf{L}_{\Theta} \mathbf{E}$; $\mathbf{E} = \mathbf{W} - \hat{\mathbf{W}} = \mathbf{Y} - \hat{\mathbf{Y}}$; and $\mathbf{\Theta} = \mathbf{L}_{\Theta} \mathbf{D} \mathbf{L}_{\Theta}'$, where $\mathbf{L}_{\Theta}$ is a lower triangular band matrix with the same lower bandwidth as $\mathbf{\Theta}$. The forecast errors $\{e_t\}$ converge to the noise $\{a_t\}$ and $\lambda_{t,t-j}$ converges to $-\theta_j$ as t increases, so that one can switch from equation (5) to equation (4) as soon as equation (4) becomes sufficiently accurate. Note also that $\mathbf{W} = \mathbf{\Phi}(\mathbf{Y} - \boldsymbol{\mu})$, where $\mathbf{\Phi}$ is the lower triangular band matrix with bandwidth p having ones in the diagonal; elements $\Phi_{i,i-k} = -\phi_k$ for $i = p+1, \dots, n$ and $k = 1, \dots, p$; and zeros elsewhere. Then $\mathbf{\Theta} = \mathbf{\Phi} \mathbf{\Omega} \mathbf{\Phi}'$ and $\mathbf{L}_{\Theta} = \mathbf{\Phi} \mathbf{L}_{\Omega}$.

This method can also be applied to ARIMA models provided that limiting formulas are used.

For example, for ARMA(p, q) models with constant mean μ , the MMSE forecast of y_2 given y_1 is $\hat{y}_2 = \mu + \rho_1(y_1 - \mu)$ and the variance of the forecast error is $D_{22} = \gamma_0(1 - \rho_1^2)$. Hence, for ARIMA($p, 1, q$) models, $\hat{y}_2 = y_1$ with forecast error variance $\lim_{\rho_1 \rightarrow 1} D_{22} = \text{var}(\nabla y_1)$.

MMSE forecasts $\hat{y}_{t|t-k}$ of y_t at origin $t - k$ for any lead time $k > 1$ are found replacing equation (4) by $\hat{y}_{t|t-k} = \sum_{i=1}^{k-1} \varphi_i \hat{y}_{t-i|t-k} + \sum_{i=k}^{p+d} \varphi_i y_{t-i} - \sum_{i=k}^q \theta_i a_{t-i}$; the forecast error is $e_{t|t-k} = y_t - \hat{y}_{t|t-k}$ and $\text{var}(e_{t|t-k}) = \sigma^2 \sum_{i=0}^{k-1} \psi_i^2$. Equation (5) can also be adapted to forecast y_t at origin $t - k$ by taking $\mathbf{Y}' = (y_1, \dots, y_{t-k}, y_t)$. Thus $\hat{y}_{t|t-k} = \sum_{j=1}^{t-k} \lambda_{tj} e_j$ and $\text{var}(e_{t|t-k}) = \sum_{j=t-k+1}^t \lambda_{tj}^2 D_{jj}$. For ARMA(p, q) models with constant μ , $\hat{y}_{k+1|1} = \mu + \rho_k(y_1 - \mu)$ and $\text{var}(e_{k+1|1}) = \gamma_0(1 - \rho_k^2)$. For ARIMA($p, 1, q$) models, $\hat{y}_{k+1|1} = y_1$ and $\text{var}(e_{k+1|1}) = k\text{var}(\nabla y_1) + 2 \sum_{i=1}^{k-1} (k-i)\text{cov}(\nabla y_1, \nabla y_{1-i})$.

Figure 2 shows the last 11 observations in the time series of Figure 1 together with the MMSE forecasts $\hat{y}_{t+k|t}$ of y_{t+k} at origin $t = 200$ for lead times $k = 1, \dots, 5$ and corresponding probability limits for each individual y_{t+k} at ± 2 standard deviations.

Process Control: Process Monitoring and Process Adjustment

Quality control is often implemented by the complementary use of process monitoring and process adjustment [2, 5]. *Process monitoring* is a part of statistical process control (SPC) and assumes that the process has already been brought to a state of stationary control by using techniques such as the standardization of materials, machines, and methods. The purpose of monitoring is to *guarantee* that the process stays in its stationary state. Hence stationary time series models are used. *Process adjustment* is primarily used when current efforts to bring the process to a state of stationary control have failed. The purpose is to determine when and by how much the process should be adjusted to attain stationarity. This can be implemented by sequentially forecasting the deviation from the target and compensating for this deviation by adjusting an input variable when and as required (see **Feedback Control**). Nonstationary and stationary time series models are used to describe the dynamics of the unadjusted and adjusted processes, respectively.

Process monitoring and process adjustment require that data should be taken routinely at equally spaced

periods of time separated by the so-called unit sampling interval. The determination of the optimal length of this sampling interval is important. It may also be appropriate to change the length of the sampling interval depending on the recent behavior of the process. Hence it is useful that the models used for process control are *invariant* to changes in the length of the sampling interval (only the model parameters may change).

In *process monitoring*, stationary ARMA models that are invariant to the length of the sampling interval are used. The basic type of these models is the white noise $y_t = \mu + a_t$, where the observed process $\{y_t\}$ has mean μ , which should be equal to the target value, and the white noise series $\{a_t\}$ is a disturbance. Alternative invariant models are the ARMA(1, 1) $y_t - \mu = \phi(y_{t-1} - \mu) + a_t - \theta a_{t-1}$ with $0 < \phi < 1$, and the AR(1) with $\theta = 0$.

In *process adjustment*, nonstationary ARIMA models that are invariant to the length of the sampling interval are used. The basic type of these models is the random walk $y_t = y_{t-1} + a_t$, used by Taguchi *et al.* [10] to model drifting observed processes. Box and Luceño [2] consider that the random walk is often too nonstationary for process adjustment applications and use the IMA(0, 1, 1) model instead. Luceño *et al.* [11] and [5] use the IMA(0, 1, 1) with trend $y_t = \beta + y_{t-1} + a_t - \theta a_{t-1}$, which is also invariant and has parameters θ and β to deal with different degrees of nonstationarity and the trend of unadjusted processes.

Fitting ARIMA Models

The approach suggested by Box and Jenkins [3, 12] is often used to fit ARIMA models to finite time series. It has three steps: model identification, model estimation, and model diagnostic.

Model Identification

Suppose that a series $\mathbf{Y}' = (y_1, \dots, y_n)$ has been observed. The first step is to decide whether it is a stationary or an integrated time series. This decision is often made by visual inspection of plots of the time series and its autocorrelation function, as well as similar plots for the first and second difference of the series. It is also possible to use unit root tests of the type introduced in [13]. The following estimators are applied

Figure 2 Observations in the time series of Figure 1 for $t = 190, \dots, 200$ ($\times$) along with their MMSE forecasts for $t = 201, \dots, 205$ ($\circ$) with ± 2 standard deviation limits ($+$)

to the series itself and its first differences: $\bar{y} = n^{-1} \sum_{t=1}^n y_t$ for the mean, $\hat{\gamma}_0 = n^{-1} \sum_{t=1}^n (y_t - \bar{y})^2$ for the variance,

$$\hat{\gamma}_k = \frac{1}{n} \sum_{t=1}^{n-k} (y_t - \bar{y})(y_{t+k} - \bar{y}) \quad (k \geq 0) \quad (6)$$

for the autocovariances, and $r_k = \hat{\gamma}_k / \hat{\gamma}_0$ for the autocorrelations. If the sample autocorrelation function of the original or differenced series has only its first q coefficients significantly different from zero, one can tentatively assume an $MA(q)$ model for that series. Otherwise, one should entertain AR, ARMA, or ARIMA models. Figure 3 shows the sample autocorrelation functions of the three time series in Figure 1. The sequence $\{r_k\}$ decreases approximately geometrically for the AR(1) series; only r_1 is clearly significantly different from zero for the MA(1) series; whereas the sequence $\{r_k\}$ decreases very slowly for the IMA(0, 1, 1) series, indicating the need to differentiate this time series.

Many statistical tools have been derived to identify the orders p , d , and q of a model: the partial autocorrelation function [3], the extended autocorrelation function [14], the inverse autocorrelation function [15, 16], and so on. However, because the estimation of ARMA models is nowadays fast and reliable, we recommend that all possible models compatible with the observed autocorrelations be estimated and that a model selection criterion be used to choose from among them (see the sections titled “Model Estimation by Maximum Likelihood”, “Joint Estimation of Missing Values and Model Parameters”, and “Model Diagnostic”).

Model Estimation by Maximum Likelihood

Let $\mathbf{Y}' = (y_1, \dots, y_n)$ be a series generated by a stationary ARMA(p, q) model $\phi_p(B)(y_t - \mu_t) = \theta_q(B)a_t$, so that $\boldsymbol{\mu}' := E(\mathbf{Y}') = (\mu_1, \dots, \mu_n)$ and $\boldsymbol{\Omega} := \text{cov}(\mathbf{Y})$. Let $\mathbf{W} := \Phi(\mathbf{Y} - \boldsymbol{\mu})$ be the working series of the section titled “Forecasting Time Series”, so that $\boldsymbol{\Theta} := \text{cov}(\mathbf{W}) = \Phi \boldsymbol{\Omega} \Phi'$, $\mathbf{W} = \mathbf{L}_{\boldsymbol{\Theta}} \mathbf{E}$,

Figure 3 Sample autocorrelation functions for each of the three time series in Figure 1

$\Theta = \mathbf{L}_\Theta \mathbf{D} \mathbf{L}_\Theta'$, $|\Omega| = |\Theta| = |\mathbf{D}|$, Φ , Θ , and $\mathbf{L}_\Theta$ are band matrices, and $\mathbf{D}$ is diagonal. For normal $\{a_t\}$, the likelihood function of the parameters $\phi' = (\phi_1, \dots, \phi_p)$, $\theta' = (\theta_1, \dots, \theta_q)$, μ , and σ^2 given $\mathbf{Y}$ is

$$\begin{aligned}
 L(\phi, \theta, \mu, \sigma^2 | \mathbf{Y}) &= (2\pi)^{-n/2} |\Omega|^{-1/2} \\
 &\quad \times \exp\{-(\mathbf{Y} - \mu)' \Omega^{-1} (\mathbf{Y} - \mu)/2\} \\
 &= (2\pi)^{-n/2} |\Theta|^{-1/2} \\
 &\quad \times \exp(-\mathbf{W}' \Theta^{-1} \mathbf{W}/2) \\
 &= (2\pi)^{-n/2} |\mathbf{D}|^{-1/2} \exp(-\mathbf{E}' \mathbf{D}^{-1} \mathbf{E}/2)
 \end{aligned} \tag{7}$$

where $|\mathbf{D}| = \prod_{i=1}^n D_{ii}$ and $\mathbf{E}' \mathbf{D}^{-1} \mathbf{E} = \sum_{i=1}^n e_i^2 / D_{ii}$. Maximum-likelihood estimates (MLEs) can be found by minimizing $-\ln[L(\phi, \theta, \mu(\beta), \sigma^2 | \mathbf{Y})]$, where μ is parameterized as $\mu(\beta)$ (see **Maximum Likelihood**).

For $\text{AR}(p)$ models, Θ equals the identity matrix excepting its first p rows and columns (and Ω^{-1} has bandwidth p); hence the MLE of ϕ' is close to its minimum sum of squared error estimate. For an $\text{AR}(1)$ model, $|\Theta|^{-1} = \sigma^{-2n} (1 -$

$\phi^2)$ and $\mathbf{W}' \Theta^{-1} \mathbf{W} \sigma^2 = C_0(1 + \phi^2) - 2\phi C_1 - \phi^2 \{(y_1 - \mu_1)^2 + (y_n - \mu_n)^2\}$, where $C_k = \sum_{t=1}^{n-k} (y_t - \mu_t)(y_{t+k} - \mu_{t+k})$; hence disregarding the effects of $|\Theta|$, y_1 , and y_n , the estimate $\hat{\phi} = C_1/C_0$ results. For $\text{MA}(q)$ models, Φ is the identity matrix, $\Omega = \Theta$ has bandwidth q , but the log-likelihood function may be far from quadratic. The MLEs for the parameters of the three time series in Figure 1 are $(\hat{\phi} = 0.765, \hat{\sigma}^2 = 0.927)$, $(\hat{\theta} = 0.838, \hat{\sigma}^2 = 0.925)$, and $(\hat{\theta} = 0.197, \hat{\sigma}^2 = 0.934)$, respectively.

Joint Estimation of Missing Values and Model Parameters

Suppose that series $\mathbf{Y}' = (y_1, \dots, y_n)$ has m missing values (see **Missing Data and Imputation**) $\mathbf{y}'_u = (y_{u_1}, \dots, y_{u_m})$, at positions $1 < u_1 < \dots < u_m < n$, having means $\mu'_u = (\mu_{u_1}, \dots, \mu_{u_m})$. Let $\mathbf{M}'$ be the $m \times n$ matrix with elements $M'_{i, u_i} = 1$, $i = 1, \dots, m$, and zeros elsewhere; and $\mathbf{B}'$ be the $(n - m) \times n$ matrix found eliminating the rows of $\mathbf{M}'$ from the $n \times n$ identity matrix. The MMSE estimator $\hat{\mathbf{y}}_u$ of the missing values is the conditional mean of $\mathbf{y}_u$ given the observations $\mathbf{B}'\mathbf{Y}$,

that is,

$$\begin{aligned}\hat{\mathbf{y}}_u &= \boldsymbol{\mu}_u + (\mathbf{M}'\boldsymbol{\Omega}\mathbf{B})(\mathbf{B}'\boldsymbol{\Omega}\mathbf{B})^{-1}\mathbf{B}'(\mathbf{Y} - \boldsymbol{\mu}) \\ &= \boldsymbol{\mu}_u - (\mathbf{M}'\boldsymbol{\Omega}^{-1}\mathbf{M})^{-1}(\mathbf{M}'\boldsymbol{\Omega}^{-1}\mathbf{B})\mathbf{B}'(\mathbf{Y} - \boldsymbol{\mu})\end{aligned}\quad (8)$$

The two formulas in equation (8) are equivalent, but the latter (using $\boldsymbol{\Omega}^{-1}$) is usually much faster than the former (using $\boldsymbol{\Omega}$) as $m \ll n - m$ [17–19]. Moreover, $\text{cov}(\mathbf{y}_u) = \mathbf{M}'\boldsymbol{\Omega}\mathbf{M}$, $\text{cov}(\mathbf{y}_u - \hat{\mathbf{y}}_u) = (\mathbf{M}'\boldsymbol{\Omega}^{-1}\mathbf{M})^{-1}$, and $\text{cov}(\hat{\mathbf{y}}_u) = \mathbf{M}'\boldsymbol{\Omega}\mathbf{M} - (\mathbf{M}'\boldsymbol{\Omega}^{-1}\mathbf{M})^{-1}$. For AR(p) models with $\boldsymbol{\mu} = 0$, equation (8) yields $\hat{y}_u = -\sum_{k=1}^p \alpha_k(y_{u-k} + y_{u+k})/\alpha_0$, if $m = 1$ and $p < u \leq n - p$, where $\alpha_k = \sum_{j=0}^{p-k} \phi_j \phi_{j+k}$ and $\phi_0 = -1$. The sequence $\{\alpha_k/\alpha_0\}$ is called the *inverse autocorrelation function* of the AR(p) model. Moreover, equation (8) accounts for end effects if $u \leq p$ or $u > n - p$.

Defining $\hat{\mathbf{Y}} = \mathbf{Y} + \mathbf{M}(\hat{\mathbf{y}}_u - \mathbf{y}_u)$ and using $\boldsymbol{\Omega}^{-1} = \boldsymbol{\Phi}'\boldsymbol{\Theta}^{-1}\boldsymbol{\Phi} = \boldsymbol{\Phi}'\mathbf{L}_{\Theta}^{-1}\mathbf{D}^{-1}\mathbf{L}_{\Theta}\boldsymbol{\Phi}$, one can efficiently obtain [17–20] MLEs of $\boldsymbol{\phi}$, $\boldsymbol{\theta}$, $\boldsymbol{\mu}$, and σ^2 maximizing

$$\begin{aligned}L(\boldsymbol{\phi}, \boldsymbol{\theta}, \boldsymbol{\mu}, \sigma^2 | \mathbf{B}'\mathbf{Y}) \\ &= (2\pi)^{-(n-m)/2} (|\boldsymbol{\Omega}| |\mathbf{M}'\boldsymbol{\Omega}^{-1}\mathbf{M}|)^{-1/2} \\ &\quad \times \exp\{-(\hat{\mathbf{Y}} - \boldsymbol{\mu})'\boldsymbol{\Omega}^{-1}(\hat{\mathbf{Y}} - \boldsymbol{\mu})/2\}\end{aligned}\quad (9)$$

This procedure can also be applied to integrated series replacing $(\mathbf{M}'\boldsymbol{\Omega}^{-1}\mathbf{M})^{-1}(\mathbf{M}'\boldsymbol{\Omega}^{-1}\mathbf{B})$ by $(\mathbf{M}'_d\boldsymbol{\Omega}_d^{-1}\mathbf{M}_d)^{-1}(\mathbf{M}'_d\boldsymbol{\Omega}_d^{-1}\mathbf{B}_d)$ in equation (8), where $\boldsymbol{\Omega}_d := \text{cov}(\mathbf{Y}_d)$, and $\mathbf{Y}'_d$, $\mathbf{M}'_d$, and $\mathbf{B}'_d$ are obtained differencing d times the rows of $\mathbf{Y}'$, $\mathbf{M}'$, and $\mathbf{B}'$. Thus, for an ARIMA($p, 1, q$), if y_3 is missing, $\mathbf{Y}_1$ has two unknown values ($y_3 - y_2$ and $y_4 - y_3$) that require only one row of length $n - 1$ in $\mathbf{M}'_1$, namely, $(0, 1, -1, 0, \dots, 0)$, the first difference of $(0, 0, 1, 0, 0, \dots, 0)$. Moreover, $\mathbf{B}_1\mathbf{B}'\mathbf{Y} = (y_2 - y_1, -y_2, y_4, y_5 - y_4, \dots)'$. Thus, for a random walk, $\hat{y}_3 = (y_2 + y_4)/2$.

Model Diagnostic

This stage is designed to check if the **residuals** of the estimated models behave approximately as white noise series and to select the best models among those verifying this condition. If a model is correct, the autocorrelation coefficients $\hat{r}_k$ of its residuals $(\hat{a}_1, \dots, \hat{a}_n)$ should asymptotically be normal variables with zero mean and variance $1/n$. Ljung and Box [21] propose the test statistic $Q(h) = n(n+2)$

$\sum_{k=1}^h \hat{r}_k^2/(n-k)$, which, for large n , follows a χ^2 distribution with $h - \nu$ **degrees of freedom**, where ν is the number of parameters $\{\boldsymbol{\phi}, \boldsymbol{\theta}, \boldsymbol{\mu}\}$ estimated in equation (7).

Peña and Rodriguez [22] propose a test statistic that can be up to 50% more powerful than the one proposed by Ljung and Box. The new statistic is $D_h = -n(h+1)^{-1} \ln |\hat{\mathbf{R}}_h|$, where $\hat{\mathbf{R}}_h$ is an $h \times h$ matrix of residual autocorrelations with elements $\hat{r}_{|i-j|}$. The asymptotic distribution of D_h is gamma with mean $h/2 - \nu$ and variance $h(2h+1)/(3h+3) - 2\nu$.

The selection among the fitted models whose residuals behave approximately as white noise series can be based on *model selection criteria*. Akaike [23, 24] proposes the selection of the model that leads to the smallest out-of-sample forecast error and shows that this is equivalent to minimizing $AIC = n \ln \hat{\sigma}_{MV}^2 + 2\nu$, where $\hat{\sigma}_{MV}^2$ is the MLE of the residual variance. Using a Bayesian approach, Schwarz [25] proposes a criterion that selects the model with highest posterior probability by minimizing $BIC = n \ln \hat{\sigma}_{MV}^2 + \nu \ln n$. See [26] for a comparison of the performance of these criteria for model selection.

Atypical Values

Time series data are often subject to outliers or discordant observations (*see Outliers*). Their study has been approached from two points of view. The first is the *diagnostic approach*, in which outliers are identified by using the residuals of the estimated model and their effect is tested afterward. A model incorporating the identified outliers is proposed, and the outlier effects and model parameters are estimated jointly. The second is the *robust approach*, in which the estimation method is modified so that the estimators are insensitive to the presence of outliers. Outliers can be easily identified and tested using these robust estimators. Both methodologies complement each other, and ideas from one approach can be used to improve the other.

Fox [27] defines additive outliers (AOs) and innovative outliers (IOs) in time series and proposes the use of maximum-likelihood ratio tests for detecting them. An AO corresponds to an external error or exogenous change of the observed value of the time series at a particular time point T ; that is, instead of observing the series $\{y_t\}$, a new series $\{z_t\}$ is observed which differs from $\{y_t\}$ by the magnitude

ω_A of the AO only at the time T of occurrence of the outlier. The model for the observed series is $z_t = \omega_A I_t^{(T)} + \Psi(B)a_t$, where $I_t^{(T)} = 0$ for $t \neq T$, $I_T^{(T)} = 1$, and $\Psi(B) = \nabla^{-d} \phi_p^{-1}(B) \theta_q(B)$ is the ARIMA model for the outlier-free time series.

An AO can be interpreted as a measurement error at time T , $1 \leq T \leq n$, or as an impulse effect due to exogenous causes. Thus if the original series is the output from a system, an AO may correspond to an unexpected event that happens at T , such as a strike, an accident, or a breakdown, which modifies the output of the system at T , without further effects on the future values of the series. AOs can have a very serious effect on the properties of the observed series [9]. In SPC, AOs are monitored using Shewhart or CUMulative SCORE (CUSCORE) charts (*see Control Charts, Overview*).

The second type of outliers introduced in [27], IO, can be generated by some internal change or endogenous effect on the time series which appears as an outlier on the process noise. The model for an IO is built by adding an impulse effect to the noise of the original process, that is, $z_t = \Psi(B)(\omega_I I_t^{(T)} + a_t)$, where ω_I is the outlier size. IOs are expected to produce small effects on the sample autocorrelation function and the parameter estimates.

A third important type of outlier in time series is a level shift, that is, a modification of the local mean or level of the process starting at time T and continuing afterward. The model for the observed series is $z_t = \omega_L S_t^{(T)} + \Psi(B)a_t$, where $S_t^{(T)} = 0$ for $t < T$, $S_t^{(T)} = 1$ for $t \geq T$ (a step function), and ω_L is the magnitude of the shift. In SPC, level shifts are monitored using CUMulative SUM (CUSUM), exponentially weighted moving average (EWMA), or CUSCORE charts (*see Exponentially Weighted Moving Average (EWMA) Control Chart; Cumulative Sum (CUSUM) Chart*).

Several procedures for outlier detection have been proposed [28–33] after the seminal work of Chang *et al.* [34]; see [9] for a revision of some of these procedures.

Model Strengths and Weaknesses

Some strengths of ARIMA models are (a) they provide a very flexible family of models, which is closed to model addition; (b) the properties of the model are well understood and simple to use; (c)

their short-term forecasts are difficult to beat with more complex models; and (d) they can be easily generalized (e.g., they can generate time irreversible series using nonnormal noise).

Some weaknesses of ARIMA models are (a) they provide little help for long term forecasting; (b) exponential smoothing is easier to use and can often provide convenient approximations to reality and forecasts nearly as good as those of full *fitted* ARIMA approximations; and (c) the framework of ARIMA models may be inconvenient to handle (e.g., most models are not invariant to changes in the sampling interval, which is important for process control; or to temporal aggregation, which is important in economy).

Related Topics

ARIMA models can be generalized to incorporate long memory (ARIMA with fractional differencing or auto-regressive fractionally integrated moving average (ARFIMA) models [35, 36]); conditional **heteroscedasticity** (generalized auto-regressive conditional heteroscedasticity (GARCH) models [37]); nonlinearity (e.g., threshold AR models [38, 39]); and information from related simultaneous series (vector ARMA, ARIMA and cointegrated models [8, 40–44]).

The analysis of time series presented here is called time-domain analysis. Time series can also be analyzed using the frequency-domain approach in which Fourier transforms of the series and its autocovariance function are used. Bayesian models can also be used.

An important alternative to ARIMA models are the so-called state space or structural dynamic models [45–48]. In these models, the time series $\{y_t\}$ is represented as a linear function $y_t = h'_t \alpha_t + a_t$ of some unknown state parameters α_t , which are assumed to follow the equation $\alpha_t = A_t \alpha_{t-1} + u_t$, with appropriate noise series $\{a_t\}$ and $\{u_t\}$. The estimation and forecasting of these models are based on the *Kalman filter algorithm* [45, 46, 49].

Appendix 1: Evaluation of Some Useful Covariances

The autocovariance function $\gamma_k := \text{cov}(y_t, y_{t+k})$ may be computed efficiently using the formula

$\sum_{i=0}^p \phi_i \gamma_{|i-j|} = \sum_{i=0}^q \theta_i \gamma_{ay}(j-i)$, where $\phi_0 = \theta_0 = -1$ and $\gamma_{ay}(-k) := \text{cov}(a_t, y_{t+k}) = \psi_k \sigma^2$ for $k \geq 0$. For $j = 0, \dots, p$, the formula provides a linear system having solution $\gamma_0, \dots, \gamma_p$; for $j > p$, it can be used recursively. The covariances $\gamma_{ay}(-k)$ are null for $k < 0$ and satisfy the recursion $\gamma_{ay}(-k) = -\theta_k \sigma^2 + \sum_{i=1}^p \phi_i \gamma_{ay}(-k+i)$ for $k \geq 0$.

Appendix 2: Covariance Matrix of Working Series W

The covariance matrix Θ of the working series $\mathbf{W}' = (w_1, \dots, w_n)$ defined in the section titled “Forecasting Time Series” and used in the section titled “Model Estimation by Maximum Likelihood” is a band matrix having bandwidth $\max(p-1, q)$ in their p first rows and q thereafter, because $w_t = y_t$ for $t = 1, \dots, p$ and $w_t = \theta_q(B)a_t$ for $t = p+1, \dots, n$. Their elements are $\Theta_{ij} = \gamma_{|i-j|}$ for $i, j = 1, \dots, p$; $\Theta_{ij} = \Theta_{ji} = -\sum_{k=1}^q \theta_k \gamma_{ay}(j-i-k)$ for $i = 1, \dots, p$ and $j = p+1, \dots, n$, where γ_{ay} is given in Appendix 1; and $\Theta_{ij} = \sigma^2 \sum_{k=|j-i|}^q \theta_k \theta_{k-|j-i|}$ for $i, j = p+1, \dots, n$, where $\theta_0 = -1$.

Process Capability, Error in Estimation of

Introduction

The inevitable variations in process measurements come from two sources: the manufacturing process and the gauge. Gauge capability reflects the gauge's precision, or lack of variation, but is not the same as **calibration**, which assures the gauge's accuracy. Process capability measures the ability of a manufacturing process to meet preassigned specifications. Nowadays, many customers use process capability to judge a supplier's ability to deliver quality products. Suppliers ought to be aware of how gauges affect various process capability estimates.

The gauge capability includes two components of **measurement systems** variability: repeatability and reproducibility. Repeatability represents the variability from the gauge or measurement instrument when it is used to measure the same specimen (with the same operator or setup or in the same time period). Reproducibility reflects the variability arising from different operators, setups, time periods, or in general, different conditions. These studies are often referred to as *gauge repeatability and reproducibility* (GR&R) studies. To summarize we have

$$\begin{aligned}\sigma_{\text{measurement error}}^2 &= \sigma_{\text{gauge}}^2 \\ &= \sigma_{\text{repeatability}}^2 + \sigma_{\text{reproducibility}}^2\end{aligned}\quad (1)$$

Estimates for $\sigma_{\text{repeatability}}^2$ and $\sigma_{\text{reproducibility}}^2$ come from a gauge study, or a GR&R study. Barrentine [1], Levinson [2], and Montgomery [3, 4], among others, provided procedures for GR&R studies.

Gauge capability is a gauge's ability to repeat and reproduce measurements. Its measurement is the percentage of tolerance consumed by (gauge) capability. Montgomery [4] referred to it as the *precision-to-tolerance* (or P/T) ratio. It is the ratio of the gauge's variation to the specification width; its smaller numbers are of course preferable. Denoting the gauge's standard deviation by σ_{gauge} , we have

$$P/T = \frac{6\sigma_{\text{gauge}}}{USL - LSL} \times 100\% \quad (2)$$

where USL and LSL represent the upper and lower specification limits, respectively. Some authors and

practitioners use the coefficient 5.15 instead of 6 (see, e.g. Barrentine [1] and Levinson [2, 5]). This formula uses 6σ as the natural tolerance width for the gauge, based on and motivated by the **normal distribution** assumptions. Values of the estimated ratio P/T of 0.1 or less often are taken to imply adequate gauge capability. This is based on the generally used rule that requires a measurement device to be calibrated in units one-tenth as large as the accuracy required in the final measurement.

GR&R studies focus on quantifying the measurement errors. Common approaches to GR&R studies, such as the range method [6] and the **ANOVA** (analysis of variance) method [7, 8], assume that the distribution of the measurement errors is normal with a mean error of zero. Let the measurement errors be described by a random variable $M \sim N(0, \sigma_M^2)$, Montgomery and Runger [6] presented the gauge capability λ by means of the formula:

$$\lambda = \frac{6\sigma_M}{USL - LSL} \times 100\% \quad (3)$$

For the measurement system to be deemed acceptable, the variability in the measurements due to the measurement system ought to be less than a predetermined percentage of the engineering tolerance. The recommended guidelines for gauge acceptance are presented in the Automotive Industry Action Group (AIAG) Measurement Systems Analysis (**MSA**) manual. The purpose of a GR&R study is to determine if the variability of the measurement system is small relative to the variability of the monitored process. Several commonly reported ratios (functions of parameters of interest) in GR&R studies are discussed in Burdick *et al.* [9]. Burdick *et al.* [9] also provided a review of methods for constructing measurement systems capability studies with emphasis on the ANOVA approach to analyze the results. More recently, Burdick *et al.* [10] applied the generalized inference methods to construct **confidence intervals** for assessing the ability of a measurement system to correctly classify parts in a GR&R study. The reported simulation suggests that, for appropriately sized experiments, the proposed method provides two-sided intervals and upper bounds that generally maintain the stated confidence level.

Process capability indices (PCIs) are convenient and powerful tools for measuring process performance. In recent years, PCIs have received considerable research attention in the quality assurance and statistical literature. Those indices quantify process performance by taking into consideration process location, process variation, and manufacturing specifications, which reflect process consistency, process accuracy, **process yield**, and process loss. A substantial majority of capability research works that appeared in the literature do not take into account gauge measurement errors. However, the gauge measurement errors have a significant effect on estimating and assessing process capability since measurement systems are not 100% precise. An inaccurate measurement system can thwart all the benefits of improvement endeavors resulting in poor quality. Analyzing process capability without considering gauge capability may often lead to unreliable decisions. It could result in a serious loss to producers if gauge capability is not being considered in process capability **estimation** and testing. On the other hand, improving the gauge measurements and having properly trained operators can reduce the measurement errors. Since measurement errors unfortunately cannot be avoided, using appropriate confidence coefficients and power becomes an essential task. However, the reality is that no measurement is free from error or uncertainty even if it is carried out with the aid of highly sophisticated and precise measuring instruments. Montgomery and Runger [6] pointed out that the quality of the data related to the process characteristics relies substantially on the gauge. Any variation in the measurement process has a direct impact on the ability to execute sound judgment about the manufacturing process. Conclusions about capability of a process based only on the single numerical value of the index are not reliable. Analyzing the effects of measurement errors on PCIs, Mittag [11, 12] and Levinson [2] developed very definitive techniques for quantifying the percentage error in PCIs estimation in the pence of measurement errors. Bordignon and Scagliarini [13] studied the inferential properties of the estimators of C_p and C_{pk} when observations are contaminated by measurement errors, while Scagliarini [14] analyzed the properties of the estimator of C_p for autocorrelated data in the presence of measurement errors. Bordignon and Scagliarini [15] studied the properties of the estimator of C_{pm} when observations

are affected by measurement errors. They compared the performances of the estimator on the error case with those of the estimator in the error-free case. The results indicated that the presence of measurement errors in the data leads to different behavior of the estimator according to the entity of the error variability.

Estimating Process Capability with Measurement Errors

Most research works related to PCIs are carried out under the assumption of no gauge measurement errors. Unfortunately, such an assumption does not adequately accommodate real-world situations even with modern, highly sophisticated measuring instruments and devices. In this section, we have emphasized constructing confidence intervals and testing procedures on the most widely used index C_{pk} in presence of gauge measurement errors.

Let $X \sim N(\mu, \sigma^2)$ represent the relevant quality characteristic of a manufacturing process and C_{pk} measure the “true” process capability. However, in practice, we deal with the observed variable Y rather than with the “true” variable X . Assume that X and M (the measurement error) are stochastically independent. In this case, we have $Y \sim N(\mu_Y = \mu, \sigma_Y^2 = \sigma^2 + \sigma_M^2)$, and the empirical process capability index C_{pk}^Y will be obtained after substituting σ_Y for σ . The relationship between the true process capability $C_{pk} = \min\{(USL - \mu)/3\sigma, (\mu - LSL)/3\sigma\} = d - |\mu - m|/(3\sigma)$ and the empirical process capability C_{pk}^Y can be expressed as follows:

$$\frac{C_{pk}^Y}{C_{pk}} = \frac{1}{\sqrt{1 + \lambda^2 C_p^2}} \quad (4)$$

where $d = (USL - LSL)/2$ refers to the half-length of the allowable tolerance of the process, $m = (USL + LSL)/2$ is the midpoint of the specification interval, $C_p = d/3\sigma$, and λ is the gauge capability index.

Since the variation of the observed data is larger than the variation of the original one, the denominator of the index C_{pk} becomes larger, and the true capability of the process will be understated if calculations of PCIs are based on the empirical data Y (the observed measurement contaminated with errors). Suppose that the empirical data

$\{Y_i, i = 1, 2, \dots, n\}$ is available, then the natural estimator

$$\hat{C}_{pk}^Y = \frac{d - |\bar{Y} - m|}{3S_Y} \quad (5)$$

obtained by replacing the process mean μ and the process standard deviation σ by their conventional estimators $\bar{Y} = \sum_{i=1}^n Y_i/n$ and $S_Y = \left[\frac{\sum_{i=1}^n (Y_i - \bar{Y})^2}{(n-1)} \right]^{1/2}$, from a stable process. Accordingly, applying the technique used in Kotz and Johnson [16] and Pearn and Lin [17], the cumulative distribution function (CDF) of $\hat{C}_{pk}^Y$ is obtained as follows:

$$\begin{aligned} F_{\hat{C}_{pk}^Y}(x) &= 1 - \int_0^{3C_p^Y \sqrt{n}} G \left(\frac{(n-1)(3C_p^Y \sqrt{n} - t)^2}{9nx^2} \right) \\ &\quad \times \phi[t + 3(C_p^Y - C_{pk}^Y)\sqrt{n}] \\ &\quad + \phi[t - 3(C_p^Y - C_{pk}^Y)\sqrt{n}] dt \end{aligned} \quad (6)$$

where $C_p^Y = \frac{C_p}{\sqrt{1+\lambda^2 C_p^2}}$, $C_{pk}^Y = \frac{C_{pk}}{\sqrt{1+\lambda^2 C_p^2}}$, $\phi(\cdot)$ is the probability density function (PDF) of the standard normal distribution, and, as above, $\lambda = 6\sigma_M/(USL - LSL) \times 100\%$.

To determine whether a given process meets the preset capability requirement, we could consider the statistical testing with the null hypothesis $H_0: C_{pk} \leq c$ (the process is not capable) and the alternative hypothesis $H_1: C_{pk} > c$ (the process is capable), where c is the required capability level. If the calculated process capability is greater than the corresponding critical value, we reject the null hypothesis and conclude that the process is capable.

Discussions in Pearn and Liao [18] indicated that the true process capability would be severely underestimated if $\hat{C}_{pk}^Y$ is used. The probability that $\hat{C}_{pk}^Y$ is greater than c_0 would be less than when using $\hat{C}_{pk}$. Thus, the α risk of using $\hat{C}_{pk}^Y$ is less than the α risk of using $\hat{C}_{pk}$ when estimating C_{pk} . The power of the test based on $\hat{C}_{pk}^Y$ is also less than that of the one based on $\hat{C}_{pk}$; that is, the α risk and the power of the test decrease when the gauge measurement error increases. Since the lower confidence bound is severely underestimated and the power becomes small, producers cannot firmly state that their processes meet the capability requirement even if their processes are indeed sufficiently

capable. Adequate and even superior product units could be incorrectly rejected in this case. To remedy the situation, Pearn and Liao [18] considered the adjustment of the confidence bounds and of the critical values to provide a superior capability assessment. Suppose that the desired confidence coefficient is θ , the adjusted confidence interval of C_{pk} with the lower confidence bound L^* , can be shown to be

$$\begin{aligned} \theta &= P(C_{pk} > L^*) \\ &= 1 - \int_0^{b^* \sqrt{n}} G \left(\frac{(n-1)(b^* \sqrt{n} - t)^2}{9n(\hat{C}_{pk}^Y)^2} \right) \\ &\quad \times [\phi(t + \xi^Y \sqrt{n}) + \Phi(t - \xi^Y \sqrt{n})] dt \end{aligned} \quad (7)$$

where $b^* = \frac{3L^*}{\sqrt{1+\lambda^2 C_p^2}} + |\xi^Y|$ and $\xi^Y = 3(C_p^Y - C_{pk}^Y)$. To eliminate the need for estimating ξ^Y , Pearn and Liao [18] followed the technique of Pearn and Shu [19] (by setting $\xi^Y = 1.00$) to find the adjusted lower confidence bound L^* , where C_p can be obtained from the equation $\frac{3(C_p - L^*)}{\sqrt{1+\lambda^2 C_p^2}} = 1.00$ as

$$\begin{aligned} C_p &= \frac{18L^* + \sqrt{324L^{*2} - 4(9 - \lambda^2)(9L^{*2} - 1)}}{2(9 - \lambda^2)} \\ &= C_{p1} \end{aligned} \quad (8)$$

To improve the power of the test, revised critical values c_0^* can be determined from

$$\begin{aligned} \alpha^* &= P(\hat{C}_{pk}^Y \geq c_0^* | C_{pk} = c) \\ &= \int_0^{3C_p^Y \sqrt{n}} G \left(\frac{(n-1)(3C_p^Y \sqrt{n} - t)^2}{9n(c_0^*)^2} \right) \\ &\quad \times \phi[t + 3(C_p^Y - C_{pk}^Y)\sqrt{n}] \\ &\quad + \phi[t - 3(C_p^Y - C_{pk}^Y)\sqrt{n}] dt \end{aligned} \quad (9)$$

where α^* is the α risk corresponding to the test using $\hat{C}_{pk}^Y$ and c_0^* , $C_p^Y = \frac{C_p}{\sqrt{1+\lambda^2 C_p^2}}$, $C_{pk}^Y = \frac{c}{\sqrt{1+\lambda^2 C_p^2}}$, and c is the capability requirement. To eliminate the need for further estimation of the characteristic parameter C_p , we set $C_p^Y = C_{pk}^Y + 1/3$ as suggested by Pearn and Lin [17], and find a reliable adjusted critical value c_0^* , where C_p can be obtained using the equation

4 Process Capability, Error in Estimation of

$\frac{C_p}{\sqrt{1+\lambda^2 C_p^2}} = \frac{c}{\sqrt{1+\lambda^2 C_p^2}} + 1/3$ as

$$C_p = \frac{18c + \sqrt{324c^2 - 4(9 - \lambda^2)(9c^2 - 1)}}{2(9 - \lambda^2)} = C_{p2} \quad (10)$$

To ensure that the α risk is within the preset magnitude, let $\alpha^* = \alpha$ and solve the above equation to obtain c_0^* . The revised power of the test (denoted by π^*) can be calculated as

$$\begin{aligned} \pi^*(C_{pk}) &= P(\hat{C}_{pk}^Y \geq c_0 | C_{pk}, C_p = C_{p2}) \\ &= \int_0^{3C_p^Y \sqrt{n}} G\left(\frac{(n-1)(3C_p^Y \sqrt{n} - t)^2}{9n(c_0^*)^2}\right) \\ &\quad \times [\phi(t + \sqrt{n}) + \Phi(t - \sqrt{n})] dt \quad (11) \end{aligned}$$

where $C_p^Y = C_p^Y + 1/3$ and $C_{pk}^Y = \frac{C_{pk}}{\sqrt{1+\lambda^2 C_{p2}^2}}$. Pearn and Liao [18] adjusted the confidence intervals and the critical values in order to ensure that the intervals possess the desired confidence coefficients and will improve the power of the test with an appropriate α risk. When estimating the capability, the estimator $\hat{C}_{pk}^Y$ severely underestimates the true capability in the presence of measurement errors. Consequently, if a statistical test is used to determine whether the process meets the capability requirement, the power of the test would decrease substantially. Consequently, lower confidence bounds and critical values ought to be adjusted to improve the accuracy of capability assessment.

An Application Example

Consider the following case taken from a manufacturing factory that makes a type of low-power, fast warm-up, and excellent stability precision voltage reference (PVR) of 15 V. The output voltage is extremely insensitive to both line and load variations and can be externally adjusted with minimal effect on drift and stability. They are ideal for communications equipment, data acquisition systems, instrumentation and process control, high-precision power supplies, and portable battery-powered equipment. Portable battery-powered equipment (Notebook computers, PDAs, DVMs, GPS,

etc.). Initial accuracy is one critical quality characteristic of this PVR which has a significant impact on the PVR quality/reliability. This characteristic is usually for room temperature only, and it provides a starting point for most of the other specifications. The output voltage tolerance of a reference is measured without a load applied after the device is turned on and warmed up. Manufacturers specify a reference with a tight initial error so that they do not have to perform room-temperature systems calibration after assembly.

For this particular model of PVR product, the specification limits are $T = m = 15$ V, $USL = 15.025$ V, and $LSL = 14.975$ V. A total of 80 observations are collected from the manufacturing process in the factory. Histograms and normal **probability plots** show that the collected data follows the normal distribution. The Shapiro–Wilk test is applied to further justify the assumption. The knowledge of the gauge capability λ is important in order to determine the effects of measurement errors on the performance of the estimator for C_{pk} . In practice, we do not know the value of λ , however, it is possible to obtain a point estimate and confidence interval through a GR&R study performed with the ANOVA method. Burdick and Larsen [20] reported the upper and lower bounds for approximate $100(1 - \alpha)\%$ confidence intervals for the parameters σ_Y^2 , σ^2 , and σ_M^2 based on modified large-sample (MLS) methods. To determine whether the process is “excellent” ($C_{pk} > 1.33$) with unavoidable measurement errors $\lambda = 0.20$ (provided by the gauge manufacturing factory), we first determine that $c = 1.33$ and $\alpha = 0.05$. Then, based on the sample data of 80 observations, we obtain the sample mean $\bar{y} = 15.0049$, the sample standard deviation $s_y = 0.0045$ ($\bar{y}$ and s_y are the realized sample values for $\bar{Y}$ and S_Y), and the point estimator $\hat{C}_{pk}^Y = 1.489$. Thus, the 95% lower confidence bound of the true process capability can be obtained as $L^* = 1.356$. Moreover, similar to the adjusted lower confidence bound, we obtain the adjusted critical value 1.464 based on $\alpha = 0.05$, $\lambda = 0.20$, and $n = 80$. Since $\hat{C}_{pk}^Y > 1.464$, we conclude that the process is “excellent”. We also see that if we ignore the measurement errors and evaluate the critical value without any correction, the critical value may be calculated as $c_0 = 1.543$. In this case we would reject that the process is “excellent” since $\hat{C}_{pk}^Y$

is not greater than the uncorrected critical value 1.543.

Conclusions

To summarize our discussion: when estimating capability the confidence bounds are substantially underestimated in the presence of measurement errors. When we use statistical testing to determine if the process meets the capability requirements, we find that the power of the test decreases with the measurement errors. Since measurement errors are, unfortunately, unavoidable in many branches of the manufacturing industry, to obtain a more accurate confidence bound and to improve the power with an appropriate α risk, adjusted confidence bounds and the critical values should definitely be applied. If the producers do not take into account the effects of the gauge capability on process capability estimation and testing, it may cause substantial and serious loss. In that case, producers are unable to affirm anymore that their processes will meet the capability requirements even if they are indeed sufficiently capable. The producers may incur substantial costs as (large) quantities of acceptable product units will be incorrectly rejected. Improving the gauge measurement accuracy and training the operators to properly execute the production procedures at each step are essential for reducing the measurement errors.

Process Capability Indices, Skewed

Introduction

The conventional process capability indices (PCIs) such as C_p , C_{pk} , C_{pm} , or C_{pmk} are usually determined under the assumption that quality characteristics follow a **normal distribution**. However, the normality assumption is usually difficult to justify and is often not appropriate in practice. For example, the measurements from drilling processes, coating processes, chemical processes, and semiconductor processes are often skewed.

In general, a process is considered to be capable if the process consistently produces items within given specifications. Therefore, many practitioners have utilized the PCIs, especially C_p or C_{pk} , in connection with the **process yield**. If a process does not follow a normal distribution, however, none of the conventional PCIs provide valid measures of the number of parts nonconforming. Table 1 gives the values of C_p as skewness (see **Skewness**) α_3 increases for Weibull, lognormal, and gamma distributions. The table also gives expected number of nonconforming

items per million (NPM) and “equivalent $C_p(EC_p)$ ” calculated by $-(1/3)\Phi^{-1}((NPM/2) \times 10^{-6})$ since $NPM \times 10^{-6} = 2\Phi(-3C_p)$ under normality, where $\Phi(\cdot)$ is the standard normal distribution function. If the value of a PCI is close to that of the equivalent C_p , the PCI describes the process capability very well. In each case in the table, it is assumed that the lower and upper specification limits (LSL and USL) are -3 and 3 , respectively, and the distribution is shifted and scaled to produce the same value of the process mean $\mu = 0$ and the standard deviation $\sigma = 1$, so that $C_p = 1$ for all cases. The table shows that the NPM increases and the EC_p decreases as skewness increases. The C_p , however, does not reflect this phenomenon and overestimates the process capability. Therefore, the index could not be used to evaluate process capability if the distribution is skewed. For more detailed discussions on the effects of nonnormality (see Somerville and Montgomery [1] and Kotz and Lovelace [2]).

Skewed PCIs to remedy the shortcoming of the conventional PCIs can be divided into five main lines: (a) To use normalizing transformations, (b) to replace the unknown distribution by an empirical distribution or by a known three- or four-parameter distribution, (c) to modify the standard definition of PCIs in order to increase their robustness, (d) to construct PCIs with the estimate of the process yield, and (e) to develop heuristic methods adequate for skewed populations.

Normalizing Transformation Method

The normalizing transformation method is the simplest way to deal with nonnormal data, which transforms original process data to normal or close to normal with some mathematical functions so that the conventional PCIs can be used. For example, if a skewed distribution becomes normal by a square root transformation, the transformed data and specification limits can be used to estimate capability indices. Such transformations include Box–Cox power transformation (see **Box and Cox Transformation**) [1] or Johnson transformation [3]. The method is easy to understand, but it may be difficult to translate the results with transformed data back to the original scale and it is likely to require considerable work due to its trial and error nature for finding a proper transformation function.

Table 1 C_p , NPM, and EC_p versus α_3

Distribution	α_3	NPM	EC_p	C_p
Normal	0.0	2700	1.00	1.00
Weibull	0.5	4227	0.95	1.00
	1.0	9870	0.86	1.00
	1.5	14 915	0.81	1.00
	2.0	18 316	0.79	1.00
	2.5	20 280	0.77	1.00
	3.0	21 256	0.76	1.00
Lognormal	0.5	5639	0.92	1.00
	1.0	10 461	0.85	1.00
	1.5	14 087	0.82	1.00
	2.0	16 358	0.80	1.00
	2.5	17 653	0.79	1.00
	3.0	18 325	0.79	1.00
Gamma	0.5	5431	0.93	1.00
	1.0	10 336	0.86	1.00
	1.5	14 782	0.81	1.00
	2.0	18 316	0.79	1.00
	2.5	20 856	0.77	1.00
	3.0	22 528	0.76	1.00

Quantile Estimation Method

Since $\mu = X_{0.5}$, $\mu - 3\sigma = X_{0.00135}$, and $\mu + 3\sigma = X_{0.99865}$ for a normal distribution, where X_p is the p th quantile (see **Quantiles**), C_p and C_{pk} can be redefined as

$$C_p = \frac{USL - LSL}{X_{0.99865} - X_{0.00135}} \quad (1)$$

$$C_{pk} = \min \left\{ \frac{USL - X_{0.5}}{X_{0.99865} - X_{0.5}}, \frac{X_{0.5} - LSL}{X_{0.5} - X_{0.00135}} \right\} \quad (2)$$

If a proper distribution can be specified, accurate measures of the three quantiles can be obtained. This involves modeling the process data with a probability model such as Weibull, lognormal, or gamma. If the variability pattern of the data cannot be described by a particular distribution, a flexible distribution approach or a nonparametric approach can be considered. The flexible distribution approach is to fit a family of distributions such as Burr or Pearson distribution to the data and use the quantiles of the fitted distribution. The nonparametric approach is to perform a nonparametric **estimation** of the quantiles. See Clements [4], Castagliola [5], and Ding [6] for the flexible distribution approach and Chang and Lu [7], Polansky [8], and **Process Capability Indices, Nonparametric**.

Clements [4] proposed to use Pearson distributions in estimating the quantiles, $X_{0.5}$, $X_{0.00135}$, and $X_{0.99865}$. These quantiles are calculated by

$$X_{0.5} = \bar{x} + z_{0.5} \cdot s \quad (3)$$

$$X_{0.00135} = \bar{x} + z_{0.00135} \cdot s \quad (4)$$

$$X_{0.99865} = \bar{x} + z_{0.99865} \cdot s \quad (5)$$

where z_p is the standardized quantile of the Pearson curve expressed as a function of skewness and **kurtosis** and can be obtained from the tables in Clements [4] and $\bar{x}$ and s are the sample mean and the sample standard deviation, respectively. The process capability can then be obtained by equations (1) and (2). Pearn and Kotz [9] applied the Clements' method to calculating second and third generation PCIs, C_{pm} and C_{pmk} , for nonnormal populations. The Clements' PCIs can be easily calculated since no complicated distribution fitting is required. Clements' approach, however, requires estimates of the third and fourth **moments** of the data and it is not possible to establish a functional relationship between Clements'

C_p and process yield that can be applied to various distributions.

Shore [10] proposed a PCI with the family of distributions introduced by Shore [11] which can be fitted with the estimated first and second moments. Note that the third and fourth moments are needed to obtain Clements' PCIs. Based on the distribution, Shore [10] suggested to calculate the three quantiles by

$$X_{0.5} = M \quad (6)$$

$$X_{0.00135} = A_1 \cdot 0.001352^{B_1} \quad (7)$$

$$X_{0.99865} = A_2 \cdot \log(739.7) + B_2 \quad (8)$$

where M is the sample median and $\{A_i, B_i\} (i = 1, 2)$ are parameters of the assumed distribution determined by the modified two-moment procedure. The **standard error** of the estimator of the Shore's PCI is fairly small, but it does not perform as well as the Clements' PCI, partly because Shore uses only the first and second moments for distribution fitting.

The reliability of the capability estimates can only be assured when the data follow at least approximately the parametric distribution being used even if a flexible distribution is assumed. To avoid this weakness of the flexible distribution method, Polansky [8] used a nonparametric approach based on the kernel technique.

The quantile estimation method can be applied to a broad range of distributions, but the method is somewhat complicated and needs considerably large samples.

Robust PCI

Pearn *et al.* [12] introduced C_θ defined as

$$C_\theta = \frac{USL - LSL}{\theta\sigma} \quad (9)$$

where θ is chosen so that the probability

$$\Pr \left\{ \mu - \frac{1}{2}\theta\sigma < X < \mu + \frac{1}{2}\theta\sigma \right\} \quad (10)$$

would be close to one and as independent as possible of the distribution. They recommended using $\theta = 5.15$ because the approximate relation

$$\Pr\{\mu - 2.575\sigma \leq X \leq \mu + 2.575\sigma\} \simeq 0.99 \quad (11)$$

varies only slightly for a number of distributions including χ^2 distributions with various **degrees of freedom**. This robustness is accomplished with the trade-off giving up the 2700 NPM for the normal population and replacing it by 10 000.

Rodriguez [13] proposed a PCI using the robust estimators of the process mean and dispersion as follows.

$$\tilde{C}_{pk} = \min \left\{ \frac{USL - \tilde{X}}{4.45MAD}, \frac{\tilde{X} - LSL}{4.45MAD} \right\} \quad (12)$$

where $\tilde{X}$ is the median of a process and MAD is the median of $(|X_1 - \tilde{X}|, \dots, |X_n - \tilde{X}|)$.

The robust method may be useful if there are insufficient data to provide accurate distribution fitting. The value of robust PCIs, however, may not coincide with that of conventional PCIs with “6 σ ” even for a normal distribution.

Process Yield Estimation Method

If $USL = \mu + k\sigma$ and $LSL = \mu - k\sigma$, a simple way to assess the process capability, is to obtain a nonconforming proportion like $p_{NC} = \Pr\{X < \mu - k\sigma \text{ or } X > \mu + k\sigma\}$, and transform the probability into the PCI using $C_p = -(1/3)\Phi^{-1}(p_{NC}/2)$. To obtain the limit of the probability for an arbitrary distribution, the Chebyshev inequality could be used, however, the limit is so broad that it is of little practical value. Flaig [14] proposed to tighten the probability bounds and estimate PCIs using an extension of the Camp–Meidell theorem. The Camp–Meidell inequality

$$\Pr\{X < \mu - k\sigma \text{ or } X > \mu + k\sigma\} \leq \frac{1}{2.25k^2} \quad (13)$$

is applicable only if the underlying distribution is unimodal and symmetrical, but he found a way to overcome this limitation. The Camp–Meidell inequality leads to the calculation of the probability that the process produces individuals outside the specification limits. It cannot be viewed as a PCI in the strict sense [2].

Chao and Lin [15] proposed to construct a PCI with an estimate of the process yield using the relation between the process yield and the C_p used under normality;

$$C_p = \frac{1}{3}\Phi^{-1} \left[\frac{1}{2} \{F(USL) - F(LSL) + 1\} \right] \quad (14)$$

where $F(\cdot)$ is the distribution function of the process. They also suggested use of a nonparametric method for estimating $F(USL)$ and $F(LSL)$ like

$$\hat{F}(x) = \frac{1}{n} \sum_{i=1}^n \Phi \left(\frac{x - X_i}{1.06 \cdot s \cdot n^{-1/5}} \right) \quad (15)$$

The nonparametric method for estimating the tail probabilities, however, does not provide accurate estimates when the sample size is small.

Heuristic Method

Wright [16] proposed a modification of C_{pmk} which incorporates a skewness term in the denominator to reduce the index value when nonsymmetry is present. Wright’s index C_s is defined as

$$\begin{aligned} C_s &= \frac{\min\{USL - \mu, \mu - LSL\}}{3\sqrt{\sigma^2 + (\mu - T)^2 + |\mu_3/\sigma|}} \\ &= \frac{(d - |\mu - T|)\sigma}{3\sqrt{1 + [(\mu - T)/\sigma]^2 + |\alpha_3|}} \end{aligned} \quad (16)$$

where T is the target, $d = (USL - LSL)/2$, and α_3 is skewness. C_s decreases as skewness increases. The index, however, cannot be related to process yield.

Chang *et al.* [17] proposed PCIs for skewed populations based on a weighted standard deviation (WSD) approach, which improves the performance of the weighted variance (WV) PCIs suggested by Choi and Bai [18]. The WSD method utilizes different divisors at the upper and lower limits of the specification interval, and the PCIs are defined as

$$C_p^{WSD} = \min \left\{ \frac{USL - LSL}{6\sigma \cdot 2P}, \frac{USL - LSL}{6\sigma \cdot 2(1 - P)} \right\} \quad (17)$$

$$C_{pk}^{WSD} = \min \left\{ \frac{USL - \mu}{3\sigma \cdot 2P}, \frac{\mu - LSL}{3\sigma \cdot 2(1 - P)} \right\} \quad (18)$$

where $P = \Pr\{X \leq \mu\}$. Wu *et al.* [19] proposed a new WV-based PCI calculated as

$$C_p^{WV} = \frac{USL - LSL}{3(S_1 + S_2)} \quad (19)$$

where $S_j^2 = 2 \sum_{i=1}^{n_j} (X_i - \bar{X})^2 / (2n_j - 1)$, n_1 is the number of observations less than or equal to $\bar{X}$, and n_2 is that greater than $\bar{X}$. The WV and WSD methods are based on the idea that the asymmetric distribution

can be divided into upper and lower parts from the process mean and the standard deviations above and below the mean can be calculated separately with the divided distributions.

The heuristic approach may not describe the capability of a process accurately. Therefore, if the type of a distribution is known or sufficient process data are available, experienced practitioners can estimate the capability fairly accurately with the data transformation or the curve fitting method. Earlier in the product life cycle, however, quality data are not sufficient. In such a case, the heuristic method may be adequate.

Multivariate PCI

Capability analyses involving more than one quality characteristic are sometimes of interests, and multivariate statistical techniques can be used to analyze several quality characteristics simultaneously. A difficulty of defining multivariate PCIs (*see Process Capability Indices, Multivariate*) in that there is no consensus on the methodology for assessing capability, which arises since the multivariate relationship among quality characteristics may or may not be reflected in the engineering specifications. In general, the upper and lower specification limits may be given for each quality characteristic and these specification ranges, taken together, form a rectangle or hypercube. Only a few methods applied to the multivariate skewed populations as well as multivariate normal populations have been suggested. For example, Polansky [20] proposed assessing the capability of a process using a nonparametric estimator based on a kernel estimate, and Chang and Bai [21] applied the WSD method to the modified region approach by Hubele *et al.* [22]. Further studies on multivariate PCIs for nonnormal populations are needed.

YOUNG SOON CHANG AND DO SUN BAI

Process Capability Indices, Nonnormal

Introduction

Process capability indices measure the ability of a process to manufacture product that meets specifications when the process is in statistical control. Most process capability studies assume that the process quality characteristic under study, X , is normally distributed. However, nonnormal process distributions are common in semiconductor and other manufacturing industries. For example, the particle counts on wafers and chemical impurity levels in semiconductor manufacturing often have nonnormal distributions. A one-sided specification is often an indication that the underlying distribution may be nonnormal. Normal distributions generally do not fit constrained data. Process capability indices for nonnormal distributions have received increasing attention in recent years. Books that devote some chapters to covering process capability indices for nonnormal distributions include Kotz and Johnson [1], Kotz and Lovelace [2], Bothe [3], and Pearn and Kotz [4]. A recent bibliography of process capability papers is given in Spiring *et al.* [5].

Many authors study the effects of nonnormality on process capability indices and conclude that using normal-based process capability indices such as C_p , C_{pu} , C_{pl} , and C_{pk} , or the equivalent superstructure $C_p(u, v)$ of Vännman [6], to analyze nonnormal data may lead to erroneous results. Somerville and Montgomery [7] investigate the errors incurred in using normal-based analysis to make inference about expected process fallout rate based on nonnormal data. Discussions of the effects of nonnormality are in Kotz and Johnson [8], Lu and Rudy [9], and Spiring *et al.* [10].

Some approaches to deal with nonnormality in process capability analysis include: (a) transforming nonnormal data to normality so that the normal-based process capability indices can be applied to the transformed data, (b) fitting data by a distribution so that quantile-related process capability indices can be evaluated, and (c) developing other non-quantile-based indices that are applicable to nonnormal distributions. Discussions of various approaches include [2] and [8].

Data Transformation

One approach to the nonnormality problem is to transform the data using some well-known transformations such as the **Box**–Cox power transformations and the Johnson system of transformations (see Box and Cox [11], Page [12], Farnum [13], Chou *et al.* [14] and Polansky *et al.* [15, 16]). A test of normality must be performed to check the normality of the transformed data. If the test supports normality, the normal-based process capability indices are appropriate for the transformed data. A powerful test of normality is given by Chen and Shapiro [17].

In a comparative study, Tang and Than [18] use the normal-based index C_{pu} as the standard and compare the performance of seven nonnormal-based indices when applied to lognormal and Weibull data. Their results show that the Box–Cox and Johnson transformation methods perform very well.

Quantile-Based Process Capability Indices

The second approach is to fit the data by an empirical distribution function or by a three or four-parameter distribution in order to obtain the **quantiles** of the distribution of X and define quantile-based process capability indices. The p th quantile of the distribution of X is defined to be a value x_p such that $\Pr(X \leq x_p) = p$. If X has a normal $N(\mu, \sigma^2)$ distribution, then $\mu = x_{0.5}$, $\mu - 3\sigma = x_{0.00135}$, and $\mu + 3\sigma = x_{0.99865}$.

The idea is to modify the usual (μ, σ) -related indices so that they are applicable to both normal and nonnormal distributions. In this approach, normal-based process capability indices are modified in order to increase their robustness (see [2]). For example, the modified index of C_p is given by

$$C'_p = \frac{USL - LSL}{x_{0.99865} - x_{0.00135}} \quad (1)$$

where LSL and USL are the lower and upper specification limits, respectively. Veevers [19] introduces the viability index which is equal to $1 - \frac{1}{C'_p}$ for any symmetric unimodal distribution.

Clements [20] suggests using a Pearson system distribution to fit the underlying distribution in order to determine the quantiles for calculating the process capability indices. The Pearson system has been used by Pearn and Kotz [21] and Bittanti *et al.* [22].

2 Process Capability Indices, Nonnormal

Castagliola [23] fits nonnormal data by a Burr distribution. Polansky applies a kernel smoothing method to fit data (see **Process Capability Indices, Nonparametric**). Krishnamoorthi and Khatwani [24] use a Weibull distribution to fit data. Ding [25] uses only the first four sample **moments** to fit the underlying distribution by a Chebyshev–Hermite polynomial up to the 10th order, where the original process data need not be available. Pal [26] uses the generalized lambda distribution to fit data. In fitting data by a distribution, a goodness-of-fit test must be performed to check if the distribution fits the data well.

Pearn and Chen [27] generalize the superstructure $C_p(u, v)$ and introduce quantile-based indices, $C_{Np}(u, v)$ and $C'_{Np}(u, v)$, for nonnormal distributions. The index $C_{Np}(u, v)$ is defined as

$$C_{Np}(u, v) = \frac{d - u|M - m|}{3\sqrt{\left(\frac{x_{0.99865} - x_{0.00135}}{6}\right)^2 + v(M - T)^2}} \quad (2)$$

where $M = x_{0.5}$, $m = (USL + LSL)/2$, $d = (USL - LSL)/2$, T is the target, and $u, v \geq 0$. $C'_{Np}(u, v)$ has exactly the same form as $C_{Np}(u, v)$ except that the median M is replaced by μ . Their study shows that the generalizations $C_{Np}(u, v)$ are superior to $C'_{Np}(u, v)$ in assessing process capability. Both indices are applicable to normal distributions since they reduce to $C_p(u, v)$. More details about the indices are in [4].

McCormack *et al.* [28] find that the empirical distribution function fits their process data very well for samples of size 100 and conclude that their index $\hat{C}_{Npk}$ is a viable estimator of process capability for nonnormal distributions, where

$$\hat{C}_{Npk} = \min\left(\frac{USL - x_{0.5}}{x_{0.995} - x_{0.5}}, \frac{x_{0.5} - LSL}{x_{0.5} - x_{0.005}}\right) \quad (3)$$

Other Process Capability Indices

The third approach to deal with nonnormality is to develop indices that are not quantile-based. The process capability index, C_{pm} , developed by Chan *et al.* [29], can be applied to assess process capability for both normal and nonnormal distributions since C_{pm} is not distribution sensitive (see [10]).

Luceno [30] introduces the index C_{pc} to handle the nonnormal data and estimate the index by an approximate **confidence interval**, where C_{pc} is defined as

$$C_{pc} = \frac{USL - LSL}{6\sqrt{\frac{\pi}{2}E|X - T|}} \quad (4)$$

A point estimator of C_{pc} is given by

$$\hat{C}_{pc} = \frac{USL - LSL}{6\sqrt{\frac{\pi}{2n} \sum_{i=1}^n |X_i - T|}} \quad (5)$$

Wright [31] proposes an index, C_s , to account for skewness (see **Process Capability Indices, Skewed**). C_s is defined as

$$C_s = \frac{\min(USL - \mu, \mu - LSL)}{3\sqrt{\sigma^2 + (\mu - T)^2 + |\mu_3/\sigma|}} \quad (6)$$

Bootstrap confidence intervals for C_s are given in Han *et al.* [32]. Nahar *et al.* [33] assess the performance of Wright's index C_s and a modified index C_{sm} , for positively skewed distribution, where C_{sm} is obtained from C_s by replacing $|\mu_3/\sigma|$ by $(-\mu_3/\sigma)$. They find that the modified Wright's index C_{sm} has some useful attributes in reflecting process performance with respect to the percent nonconforming and the accuracy for relatively large samples.

Wu and Swain [34] propose process capability indices based on the weighted variance method. Chang *et al.* [35] propose indices based on the weighted standard deviation method. The idea for both methods is to divide a skewed or asymmetric distribution into two normal distributions that have the same mean but different variances or standard deviations. Simulation studies indicate these methods are fairly consistent in estimating process fallout rate for some nonnormal distributions.

Perakis and Xekalaki [36, 37] propose an index $(1 - p_0)/(1 - p)$, where p and p_0 denote the proportion of conformance (yield) and the minimum allowable proportion of conformance of the process under study. They state that the index can be used for both continuous and discrete process distributions.

Chao and Lin [38] believe a process capability index must represent the true yield and propose a

universal index, C_y , defined as

$$C_y = \frac{1}{3} \Phi^{-1} \left[\frac{1}{2} F(USL) - F(LSL) + 1 \right] \quad (7)$$

where Φ is the standard normal distribution function and F is the distribution function of X . The index can be extended to a multivariate process capability index (see **Process Capability Indices, Multivariate**) when F is a multivariate distribution.

Future Research

Many process capability indices have been proposed for nonnormal distributions or data. Various methods of estimating a process capability index can lead to different estimates of the rate of nonconforming product. Kaminsky *et al.* [39] show that it is difficult to demonstrate that a good process is indeed a good process by using a point estimator. Information about confidence interval estimation of the process capability indices is generally lacking.

As pointed out in [10], there has been little research in the area of loss and loss functions as methods for assessing process capability. The potential problem of nonnormality leads researchers to develop new indices or investigate the properties of particular process capability indices by evaluating their estimators using a variety of nonnormal process data. A comprehensive study of the indices and situations where they are applicable seems necessary.

Process Capability Indices, Nonparametric

Introduction

A manufacturing process is considered to be capable if it consistently produces items within specifications. The consistency of a process, usually assessed using control chart techniques, is typically the first concern when studying a process (*see **Control Charts, Overview***). Once consistency has been established, a capability study then focuses on the ability of the process to produce items within specifications. While the primary focus of such a study is usually on the **process yield**, process capability indices are generally the measure used to study the capability of a process. These indices are typically unitless ratios that compare the size of the specification set to the natural variability of the process. Interpretation of the indices and their relationship to the process yield are usually reliant on specific assumptions about the distribution of the quality characteristic. The most common assumption is that the distribution of the quality characteristic follows a **normal distribution**, though indices related to other parametric distributions have been developed.

Many researchers have carefully studied examples of process data and have generally concluded that normal process data may be rare in practice [1–5]. It has also been shown that violations of the normal assumption can have a large effect on the ability of the process capability indices to properly indicate the actual capability of the process [6–8]. To address this problem, many indices have been developed to measure the capability of processes whose quality characteristics follow specific nonnormal distributions, such as the exponential and Weibull. Other indices have been developed that use more flexible families of distributions such as the Burr, Johnson, and Pearson systems (*see **Process Capability Indices, Nonnormal***). These indices are not strictly nonparametric indices in the sense that one is tacitly assuming that the distribution of the quality characteristic is within the family of distributions. Still other indices have implemented penalties for **skewness** (*see **Process Capability Indices, Skewed***).

A nonparametric process capability index is one that properly indicates the capability of a process without making specific assumptions about the form of the underlying distribution of the quality characteristic. Some relatively minor assumptions are usually made. For example, it is usually assumed that the distribution of the quality characteristic has some smoothness properties and has a certain number of finite **moments**. This article will focus on these types of methods for assessing the capability of a process. The first part of the article discusses nonparametric process capability indices. The second part of the article discusses nonparametric methods for evaluating the process yield. Alternative types of process capability indices that are a function of the process yield have been suggested by several researchers. The final part of this article addresses issues related to formal statistical inference using these methods.

Capability Indices

Consider a manufacturing process that produces units with a univariate quality characteristic X that follows an unknown distribution F with $\mu = E(X)$ and $\sigma^2 = V(X)$. Assume that the specification set for X is an interval of the form $S = (L, U) \subset \mathbb{R}$. In the usual case, where F is unknown, we consider observing a sample $X_1, \dots, X_n$ from F by randomly sampling items from the process. A typical process capability index compares the allowable variability of the process, given by the size of the specification set, to the actual process variability as a ratio. A simple measure of the allowable process variability is given by $U - L$, regardless of the form of F . The actual process variability is related to the variability of F , which is usually measured as $\theta\sigma$, where θ is chosen so that $P(X - \theta\sigma < X < \mu + \theta\sigma) \simeq 1$ [3]. Therefore, the general form of the process capability index is $C_\theta = (U - L)/\theta\sigma$, where σ is often estimated using the sample standard deviation s . When F is normal, the usual choice is $\theta = 6$. The more universal choice of $\theta = 5.15$ has also been suggested by [3]. A nonparametric index can be formed by replacing $\theta\sigma$ with the width of a 99.73% distribution-free tolerance interval for F [9]. Note that these approaches are direct analogs to the C_p (process capability index), which assumes that the process mean is centered in the specification set.

2 Process Capability Indices, Nonparametric

Otherwise, these indices merely indicate the best possible capability of the process. See Section 2.2 of [10].

The standard deviation may not be an appropriate measure of variability for all process distributions. A measure based on the **percentiles** of F has been suggested by [11]. The analog of the C_p process capability index they propose has the form

$$\hat{C}_{np} = \frac{U - L}{\hat{\xi}_{99.5} - \hat{\xi}_{0.5}} \quad (1)$$

where $\hat{\xi}_\eta$ is the η th sample percentile of the observed process data. The same authors suggest an analog of the C_{pk} index, which accounts for the location of the process distribution. This index is given by $\hat{C}_{npk} = \min\{\hat{C}_{npl}, \hat{C}_{npu}\}$, where

$$\hat{C}_{npl} = \frac{\hat{\xi}_{50.0} - L}{\hat{\xi}_{50.0} - \hat{\xi}_{0.5}} \quad (2)$$

and

$$\hat{C}_{npu} = \frac{U - \hat{\xi}_{50.0}}{\hat{\xi}_{99.5} - \hat{\xi}_{50.0}} \quad (3)$$

An empirical study presented in [11] compared the performance of the usual $\hat{C}_{pk}$ process capability index and the proposed $\hat{C}_{npk}$ index. These simulations showed that the **bias** of the $\hat{C}_{npk}$ index was lower than that of the $\hat{C}_{pk}$ index for nonnormal distributions. Similar proposals have been suggested by [12–14].

Another modification of the C_p index is suggested by [15]. The sample form of this index is

$$\hat{C}_{pc} = \frac{U - L}{6\bar{c}\sqrt{\pi/2}} \quad (4)$$

where

$$\bar{c} = n^{-1} \sum_{i=1}^n |X_i - (U + L)/2| \quad (5)$$

The choice of the denominator of this index takes advantage of the quick convergence properties of the central limit theorem so that reliable **confidence intervals** for this index are simple to compute, regardless of the form of F . While the process yield associated with this index does depend on F , it is shown by [15] that the relationship is more stable than the relationship between the C_p process capability index and the process yield.

Indices Based on the Process Yield

The process yield is defined to be $p = P(L \leq X \leq U)$, the expected proportion of items in a sample that are within specification. Several authors have suggested that process capability indices that are based on estimates of the process yield may be more useful, particularly for nonnormal process data [16–20]. The advantages of this approach are that the interpretation of the process yield does not depend on the process distribution, the indices easily generalize to the case of a multivariate quality characteristic, and that the index can be applied to discrete processes [21]. For example [20] suggests a process capability index of the form

$$C_{pc} = \frac{1 - p_0}{1 - p} \quad (6)$$

where p_0 is the minimum allowable process yield. The process fallout $q = 1 - p$ can be used as an equivalent basis for these indices. Let $q_L = P(X < L)$ and $q_U = P(X > U)$. Then [22] suggests a process capability index of the form

$$C_f = \min \left\{ \frac{q_L^0}{q_L}, \frac{q_U^0}{q_U} \right\} \quad (7)$$

where q_L^0 and q_U^0 are the maximum allowable process fallout rates below and above the specifications, respectively.

In order to implement these indices in the nonparametric setting, a reliable nonparametric method for estimating the process yield p must be used. A simple nonparametric approach consists of estimating the process yield with the proportion of items in the sample that are within specification, that is,

$$\hat{p} = n^{-1} \sum_{i=1}^n \delta(L \leq X_i \leq U) \quad (8)$$

where δ is the indicator function. Confidence limits for $\hat{p}$ are easily computed using the binomial distribution [23]. Such an interval is usually quite wide unless the sample size is very large, as the method does not take advantage of information in the sample about the form of F . Methods for computing upper bounds on p based on a modification of Tchebysh-eff's theorem have been considered by [24]. The use of extreme value theory has been suggested by [22]. Note that if F is continuous then $p = F(U) - F(L)$.

This implies that the process yield can also be estimated by replacing F with a nonparametric estimate, such as a kernel estimate [25, 26]. Bandwidth selection for this estimate can be achieved using the plug-in method of [27] or the cross validation technique of [28]. Another approach suggested by [29] takes advantage of the nearly pivotal transformation $(x - \bar{x})/s$ and the **bootstrap** to develop a nonparametric approach to estimating the process fallout rate. Using the fact that a density can be written as a series of Chebyshev–Hermite polynomials [30] derive a method for estimating process yield based only on the first four sample moments.

The Multivariate Case

The case of a multivariate quality characteristic presents challenges for any measure of process capability. This is particularly true for nonparametric process capability indices. Let $\mathbf{X}$ be a d -dimensional quality characteristic and let $S \subset \mathbb{R}^d$ be the specification set for the characteristic. It will be assumed that $\mathbf{X}$ follows a d -dimensional distribution F . In the usual sample case, $\mathbf{X}_1, \dots, \mathbf{X}_n$ will denote the quality characteristics observed from items sampled from the process.

A multivariate process capability index has been developed by [31] that is directly related to the process fallout rate. This approach requires a specification set of the form

$$S = \{\mathbf{x} \in \mathbb{R}^d : h(\mathbf{x} - \mathbf{T}) \leq r\} \quad (9)$$

where $h : \mathbb{R}^d \rightarrow \mathbb{R}^+$, $\mathbf{T}$ is a target vector, and $r > 0$ is a constant. Such a specification set is general enough to include ellipsoidal and rectangular specification sets. In this case, the process fallout rate is $q = P[h(\mathbf{X} - \mathbf{T}) > r]$, and [31] defines the multivariate process capability index as

$$MC_p = \frac{q_0}{q} \quad (10)$$

where q_0 is the maximum acceptable fallout rate. This index is generalized to the nonparametric setting by [32], who use extreme value theory to develop a nonparametric method for estimating q based on $\mathbf{X}_1, \dots, \mathbf{X}_n$. The process fallout rate can also be estimated in the nonparametric setting using a multivariate kernel density estimate. With this method, one must assume that F has an absolutely

continuous d -dimensional density f so that the process fallout rate can be written as

$$q = 1 - \int_S f(\mathbf{x}) d\mathbf{x} \quad (11)$$

The fallout rate is then estimated by replacing f with a multivariate kernel density estimate. The bandwidth for this estimate must be specifically tailored to the specific shape of S . A bootstrap method for selecting the bandwidth matrix for the kernel estimate based on observations $\mathbf{X}_1, \dots, \mathbf{X}_n$ is given by [33].

Statistical Inference

A complete plan for studying the capability of a process should include methods for reliable statistical inference, including confidence intervals and tests of hypotheses. Most of the nonparametric methods developed so far have dealt exclusively with **estimation**. The form of the estimates and the lack of assumptions of the distribution of the quality characteristic generally exclude the possibility of simple closed form inferential methods for the case of finite sample sizes. Asymptotic inference for the indices may also be problematic due to the complexity of the indices. One exception is the index proposed by [15] which was specifically designed for simple inference. In general, most of the methods discussed here may require the application of the nonparametric approaches to inference afforded by such methods as the jackknife and the bootstrap.

Basic Capability Indices

Process capability indices are becoming a common approach to report process performance, both internally and in managing customer–supplier relationships. In the univariate case, *capability indices* are defined as ratios of spread between the process specification limits to variability of the process. For the univariate case, C_p , C_{pk} , C_{pm} , and C_{pmk} are the most commonly known *process capability indices* [1–3]. Most process capability indices assume that the process performance data are normally distributed. Let μ and σ be the mean and standard deviation, respectively, of a process performance characteristic such as weight, assay, particle size, or voltage levels. Furthermore let USL, LSL, and T be the upper and lower specification limits and the target value, respectively. The above mentioned population capability indices are defined as follows:

$$C_p = \frac{USL - LSL}{6\sigma} \quad (1)$$

$$C_{pk} = \min \left[\frac{USL - \mu}{3\sigma}, \frac{\mu - LSL}{3\sigma} \right] \quad (2)$$

$$C_{pm} = \frac{USL - LSL}{6\sqrt{\sigma^2 + (\mu - T)^2}} \quad (3)$$

$$C_{pmk} = \min \left[\frac{USL - \mu}{3\sqrt{\sigma^2 + (\mu - T)^2}}, \frac{\mu - LSL}{3\sqrt{\sigma^2 + (\mu - T)^2}} \right] \quad (4)$$

with the sample estimates being obtained by replacing the population μ and σ by their sample estimates, $\bar{x}$ and s , respectively.

General Multivariate Capability Indices

However, many industrial processes have more than one performance or quality characteristic so that multivariate evaluation of process performance becomes more and more important. Although univariate process capability indices have been extensively studied in the literature, their multivariate counterparts have received relatively little attention.

Taam *et al.* [4] and later Pal [5] proposed the index $C_{pb} = S_R/A_P$, where S_R represents the surface defined by the rectangle of the upper and lower tolerances and A_P is the process surface including 99.73% of the process data. Wang and Chen [6] proposed multivariate equivalents for C_p , C_{pk} , C_{pm} , and C_{pmk} based on principal component analysis decomposition. Wang and Du [7] proposed the same indices with extension to the nonnormal multivariate case. Wang *et al.* [8] proposed a process capability multivariate vector to evaluate the process performance. Such a vector has the following components: a multivariate C_p index, the p value of a T^2 Hotelling test, and a location index. Chen [9] also investigated a method to estimate the multivariate C_p using a nonconforming proportion approach. Castagliola and Castellanos [10] propose a method for estimating both C_p and C_{pk} indices for two quality variables labeled BC_p . The proposed bivariate C_{pk} index is calculated by first finding four probabilities corresponding to the theoretical fraction of values that exceed the surface formed by the process tolerances (nonconforming proportion). They then use a numerical quadrature method based on Green's theorem for computing the probabilities associated with each convex polygon. The capability index BC_p is found by maximizing the capability index BC_{pk} , i.e. by maximizing the theoretical proportion of conforming items.

A general formulation of multivariate capability indices is based on the region $L \leq g(\mathbf{X}) \leq U$ where $g(\mathbf{X})$ is a monotonic function of the joint **probability density function** of $\mathbf{X}$ and often, L is zero. If $\mathbf{X}$ is assumed to have a multivariate normal $N_v(\boldsymbol{\mu}, \boldsymbol{\Sigma})$ distribution a natural $g(\mathbf{X})$ function is $g(\mathbf{X}) = (\mathbf{X} - \boldsymbol{\mu})\boldsymbol{\Sigma}^{-1}(\mathbf{X} - \boldsymbol{\mu})$ and one may regard an item as nonconforming if $(\mathbf{X} - \boldsymbol{\mu})\boldsymbol{\Sigma}^{-1}(\mathbf{X} - \boldsymbol{\mu}) > U$. We thus obtain the ellipsoidal specification region $(\mathbf{X} - \boldsymbol{\mu})\boldsymbol{\Sigma}^{-1}(\mathbf{X} - \boldsymbol{\mu}) \leq U$.

An analog of C_p is

$$\frac{\text{Volume of } \{(\mathbf{X} - \boldsymbol{\mu})\boldsymbol{\Sigma}^{-1}(\mathbf{X} - \boldsymbol{\mu}) \leq U\}}{\text{Volume of } \{(\mathbf{X} - \boldsymbol{\mu})\boldsymbol{\Sigma}^{-1}(\mathbf{X} - \boldsymbol{\mu}) \leq R\}} \quad (5)$$

where $\Pr[(\mathbf{X} - \boldsymbol{\mu})\boldsymbol{\Sigma}^{-1}(\mathbf{X} - \boldsymbol{\mu}) \leq R] = 1 - p$.

Again, if $\mathbf{X}$ has a multivariate **normal distribution** $(\mathbf{X} - \boldsymbol{\mu})\boldsymbol{\Sigma}^{-1}(\mathbf{X} - \boldsymbol{\mu})$ has a χ^2 distribution with ν **degrees of freedom** and $R = \chi_{\nu, 1-p}^2$ is the corresponding upper 100(1 - p)% point of the χ^2 distribution with ν degrees of freedom. For more examples of such indices see Wierda [11], Chan *et al.*

[12], Kotz and Johnson [2], Foster *et al.* [13], Pearn *et al.* [14], Pearn [15], and Pearn and Kotz [16].

Capability Indices Based on Tolerance Regions

Tolerance regions provide an alternative to the $L \leq g(\mathbf{X}) \leq U$ region, that is based on estimates of **percentiles** from a multivariate distribution with parameters either known or estimated from the data.

Fuchs and Kenett [17] suggest the establishment of a process control schema based on tolerance regions by estimating the level set $\{f \geq c\}$ with a prespecified probability content $1 - \alpha$, of the density f which generates the data. A reasonable criterion would be to reject an additional observation $\mathbf{X}_{n+1}$ whenever $\mathbf{X}_{n+1} \in \{f < c\}$, which would give an exact false alarm probability α . Since f is usually unknown, the population tolerance region $\{f \geq c\}$ can be estimated by plugging in an estimator function of f . For the multivariate normal case, Krishnamoorthy and Mathew [18] provide various estimates and clarify an inconsistency in notation adopted by John [19] and Fuchs and Kenett [17]. Baillo and Cuevas [20] develop a nonparametric solution of the procedure suggested by Fuchs and Kenett [17]. Di Bucchianico *et al.* [21] develop a nonparametric procedure for constructing multivariate tolerance regions that relies on the choice of a class of sets to which the tolerance region belongs (for example, ellipsoids or hyperrectangles). Polansky [22] also uses the tolerance regions approach to evaluate the capability of a manufacturing process.

Thus, a natural extension of process capability measures to the multivariate case builds on the concept of tolerance regions. This area is an active research area and will probably remain so in the next few years. Applying tolerance regions to the general formulation of **multivariate process capability indices** offers new definitions of process capability indicators.

Multivariate Process Capability Indices, Comparison of

Introduction

Quality measures can be used to evaluate a process's performance. In general, there are several issues that need to be discussed in assessing product quality. One important issue is the process capability index (PCI). A PCI is a numerical summary that compares the behavior of a product or process characteristic to engineering specifications. The capability indices, C_p , C_{pk} , and C_{pm} , are widely used to evaluate process performance based on a single engineering specification. However, products usually have two or more quality characteristics in processes. Thus, these univariate capability indices do not satisfy this situation, and multivariate methods for assessing process capability are needed. Process capability and related analysis have been studied for well over 20 years. Kotz and Johnson [1] provided a compact survey and brief interpretations and comments on some 170 publications on PCIs from 1992 to 2000.

In general, multivariate PCIs can be divided into two categories: the ratio of the tolerance region to the process region and the **process yield** index. In the following section, several multivariate PCIs which were proposed by Chan *et al.* [2], Pearn *et al.* [3], Taam *et al.* [4], Chen [5], Shahriari *et al.* [6], Wang and Du [7], Walter *et al.* [8], and Pearn *et al.* [9] will be reviewed. In the third section, an example is used to compare the performance of different multivariate PCIs. The conclusion is made in the final section.

Multiple Characteristics Processes and Multivariate Process Capability Indices

Multiple Characteristics Processes

In most processes, products usually have multiple quality characteristics. Each of these characteristics must satisfy its specification. So, the assessed quality of a product depends on the combined effects of these characteristics, rather than on their individual values. With respect to the tolerance region of multiple characteristics, it can be a rectangular tolerance

region for two-dimensional cases. In higher dimensions, they form a hypercube. For more complex engineering specifications, the tolerance region will be more complicated.

In most **multivariate capability indices**, it is usually assumed that the observations X have a multivariate **normal distribution**, $N_v(\mu, \Sigma)$, where v is the number of variables, μ is the mean vector, and Σ represents the variance–**covariance** matrix of X . Also, T is the target vector, upper specification limits (USL) and lower specification limits (LSL) are the specification limits, $\bar{X}$ is the sample mean vector, and S is the sample covariance matrix. For convenience, the assumption and notations are used in the following subsection.

Multivariate Process Capability Indices

Chan *et al.* [2] introduced a new version of the multivariate index C_{pm} , which is defined by

$$C_{pm} = \frac{\sqrt{\frac{nv}{n}}}{\sqrt{\sum_{i=1}^n (X_i - T)' A^{-1} (X_i - T)}} \quad (1)$$

This value indicates the **degrees of freedom** associated, while the denominator represents the sum of the observed Mahalanobis distances from the target [10]. Smaller values of C_{pm} suggest that the process is unable to meet the specifications, while larger values of C_{pm} suggest that the process is indeed capable of meeting its specifications.

Pearn *et al.* [3] introduced two multivariate PCIs ${}_vC_p$ and ${}_vC_{pm}$, which are a generalization of C_p and C_{pm} , respectively. They are defined as

$${}_vC_p = \frac{K}{\theta \chi_{v,0.9973}} \quad (2)$$

and

$${}_vC_{pm} = \frac{{}_vC_p}{\left(1 + \frac{(\mu - T)' A^{-1} (\mu - T)}{v}\right)^{1/2}} \quad (3)$$

where the region R is defined by $(X - T)' A^{-1} (X - T) \leq K^2$ and $V_0 = \theta^2 A$.

Taam *et al.* [4] proposed a multivariate capability index defined as a ratio of two volumes: $MC_{pm} =$

2 Multivariate Process Capability Indices, Comparison of

$\frac{\text{vol}(R_1)}{\text{vol}(R_2)} = \frac{\text{vol}(\text{modified tolerance region})}{\text{vol}((X - \mu)' \Sigma_T^{-1} (X - \mu) \leq k(q))}$, where R_1 is a modified tolerance region and R_2 is a scaled 99.73% process region from a multivariate normal assumption. The modified tolerance region is the largest ellipsoid that is centered at the target completely within the original tolerance region. The estimate for MC_{pm} can be expressed as

$$\begin{aligned} \widehat{MC}_{pm} &= \frac{\widehat{C}_p}{\widehat{D}} \\ &= \frac{\text{vol}(\text{modified tolerance region})}{|S|^{1/2} (\pi k)^{v/2} [\Gamma(v/2 + 1)^{-1}]} \left[1 + \frac{n}{n-1} (\bar{X} - T)' S^{-1} (\bar{X} - T) \right]^{1/2} \quad (4) \end{aligned}$$

where K is the 99.73% percent quantile of a χ^2 distribution and $|\cdot|$ denotes the determinant. The numerator $\widehat{C}_p$ is analogous to C_p , that is, a value greater than 1 implies that the process has a smaller variation than allowed by specification limits with a certain confidence level; a value less than 1 implies more variation. Similarly, $0 < 1/\widehat{D} < 1$ measures the closeness between the process mean and the target; a larger $1/\widehat{D}$ implies the mean is closer to target.

Chen [5] proposed a multivariate process index over a tolerance zone. A tolerance zone is expressed as $V = \{X \in R^v : h(X - \mu_0) \leq r_0\}$, where r_0 is a positive number and $h(X - \mu_0)$ is a cumulative distribution function. A process is capable if $P(X \in V) \geq 1 - \alpha$, where α is the allowable expected proportion of nonconforming production from a process. Let $r = \min\{c : P(h(X - \mu_0) \leq c) \geq 1 - \alpha\}$. If the cumulative distribution function of $h(X - \mu_0)$ is increasing in a neighborhood of r , then r is simply the unique root of the equation $P(h(X - \mu_0) \leq r) = 1 - \alpha$. The process is deemed capable if $r \leq r_0$, that is, $(r_0/r) \geq 1$. The multivariate process capability is defined as

$$MC_p = \frac{r_0}{r} \quad (5)$$

Shahriari *et al.* [6] proposed a multivariate capability vector, which consists of three components (C_{pM} , PV , LI). The first component of the vector is a ratio of areas or volumes, analogous to the ratio of lengths of the univariate C_p index. The denominator is the area (two-dimensional case) or the volume (three or more dimensions) defined by the engineering tolerance region, which is defined

as $C_{pM} = \left[\frac{\text{volume of engineering tolerance}}{\text{volume of modified process region}} \right]^{1/v}$. The approach forms a “modified process region” by drawing the smallest rectangle around the ellipse. The edges of the rectangle are determined by solving the equations of the first derivatives, with respect to each x_i , of the quadratic form $(X - \mu_0)' \Sigma (X - \mu_0) = \chi_{v,\alpha}^2$. Two solutions to this equation are given in the following:

$$\begin{aligned} UPL_i &= \mu_i + \sqrt{\frac{\chi_{v,\alpha}^2 \det(\Sigma_i^{-1})}{\det(\Sigma^{-1})}}, \\ LPL_i &= \mu_i - \sqrt{\frac{\chi_{v,\alpha}^2 \det(\Sigma_i^{-1})}{\det(\Sigma^{-1})}}, \quad \forall \dots i = 1, 2, \dots, v \end{aligned} \quad (6)$$

where $\chi_{v,\alpha}^2$ is the upper 100 $\alpha\%$ of a χ^2 distribution with v degrees of freedom associated with the probability contour, and $\det(\Sigma_i^{-1})$ is the determinant of Σ_i^{-1} , which is a matrix obtained from Σ^{-1} by deleting the i th row and column. As a result, the equation can be expressed as

$$C_{pM} = \left[\frac{\prod_{i=1}^v (USL_i - LSL_i)}{\prod_{i=1}^v (UPL_i - LPL_i)} \right]^{1/v} \quad (7)$$

If the value is greater than 1, then it shows that the circumscribed modified process region is smaller than the engineering specified region, that it is “acceptable”. Necessarily, the modified process region is influenced by the shape of the elliptical contour and the size of the contour. The second component is the **significance level** of the Hotelling’s T^2 statistic ($T^2 = n(\bar{X} - \mu)' S^{-1} (\bar{X} - \mu)$) which is expressed as

$$PV = Pr \left(F_{v,n-v} > \frac{n-v}{v(n-1)} T^2 \right) \quad (8)$$

where $F_{v,n-v}$ denotes a variable having the F distribution with $v, n-v$ degrees of freedom. The PV value will never exceed 1, and it indicates that the center of process is far from the engineering target value when the value is close to 0. The third component summarizes a comparison of the location of the modified process region and the tolerance region. It

has a value 1 if the entire modified process region is contained within the tolerance region and, otherwise, a value of 0. That is,

$$LI = \begin{cases} 1 & \text{if modified process region is contained} \\ & \text{within the tolerance} \\ 0 & \text{otherwise} \end{cases} \quad (9)$$

Wang and Du [7] proposed a very useful method using principal component analysis (PCA) in process performance for multivariate data. By using the spectral decomposition, we can get a matrix $D = U^T S U$, where D is a diagonal matrix. The elements of D , $\lambda_1, \lambda_2, \dots, \lambda_v$, are the eigenvalues of S and the columns of U , $u_1, u_2, \dots, u_v$ are the eigenvectors of S . So the i th principal component is expressed as $PC_i = u_i^T x$, $i = 1, 2, \dots, v$, where x s are $v \times 1$ vectors of original observations on variables. The engineering specifications and target values of PC_i s are $\begin{cases} LSL_{PC_i} = u_i^T LSL \\ USL_{PC_i} = u_i^T USL \end{cases} \forall i = 1, 2, \dots, v$. Similarly, $\begin{cases} T_{PC_i} = u_i^T T \\ S^2_{PC_i} = \lambda_i \\ \bar{X}_{PC_i} = u_i^T \bar{X} \end{cases} \forall i = 1, 2, \dots, v$. Now,

where

$$\hat{C}_{p;PC_i} = \frac{(USL_{PC_i} - LSL_{PC_i})}{6\sqrt{S^2_{PC_i}}} \quad (12)$$

and

$$\hat{C}_{pk;PC_i} = \frac{\min(USL_{PC_i} - \bar{X}_{PC_i}, \bar{X}_{PC_i} - LSL_{PC_i})}{3\sqrt{S^2_{PC_i}}} \quad (13)$$

The approximate $100(1 - \alpha)\%$ **confidence intervals** for MC_p and MC_{pk} are

$$\left[\left(\prod_{i=1}^v \hat{C}_{p;PC_i} \sqrt{\frac{\chi^2_{1-\alpha/2, n-1}}{n-1}} \right)^{1/v}, \left(\prod_{i=1}^v \hat{C}_{p;PC_i} \sqrt{\frac{\chi^2_{\alpha/2, n-1}}{n-1}} \right)^{1/v} \right] \quad (14)$$

and

$$\left[\left(\prod_{i=1}^v \hat{C}_{pk;PC_i} \left[1 - Z_{\alpha/2} \sqrt{\frac{1}{9n\hat{C}_{pk;PC_i}} + \frac{1}{2(n-1)}} \right] \right)^{1/v}, \left(\prod_{i=1}^v \hat{C}_{pk;PC_i} \left[1 + Z_{\alpha/2} \sqrt{\frac{1}{9n\hat{C}_{pk;PC_i}} + \frac{1}{2(n-1)}} \right] \right)^{1/v} \right] \quad (15)$$

only few principal components can explain most of the total variability (about 70 ~ 90%). Jackson [11] proposed a χ^2 test for identifying the significant components. Referring to this method, we can choose the suitable number of PC_i s easily. Now, the related formulas of multivariate PCIs for the multivariate normal data and non-multivariate normal data can be displayed for the following: (a) two multivariate PCIs for multivariate normal data are defined as

$$\widehat{MC}_p = \left(\prod_{i=1}^v \hat{C}_{p;PC_i} \right)^{1/v} \quad (10)$$

and

$$\widehat{MC}_{pk} = \left(\prod_{i=1}^v \hat{C}_{pk;PC_i} \right)^{1/v} \quad (11)$$

where $Z \sim N(0, 1)$, respectively. (b) The multivariate PCI for non-multivariate normal data is based on a PCI by Luceño [12], which is designed to consider both the process location and spread, as well as to provide for confidence bounds that are insensitive to departures from normality. The multivariate PCI is defined as

$$\widehat{MC}_{pc} = \left(\prod_{i=1}^v \hat{C}_{pc;PC_i} \right)^{1/v} \quad (16)$$

where $\hat{C}_{pc;PC_i} = (USL_{PC_i} - LSL_{PC_i}) / (6\sqrt{\pi/2\bar{c}})$. The approximate $100(1 - \alpha)\%$ confidence interval for MC_{pc} is

$$\left[\left(\prod_{i=1}^v \frac{\hat{C}_{pc;PC_i}}{1 + t_{\alpha, n-1} S_{C_i} / (\bar{c}_i \sqrt{n})} \right)^{1/v}, \right]$$

4 Multivariate Process Capability Indices, Comparison of

$$\left(\prod_{i=1}^v \frac{\hat{C}_{pc;PC_i}}{1 - t_{\alpha,n-1} S_{C_i} / (\bar{c}_i \sqrt{n})} \right)^{1/v} \quad (17)$$

where

$$\bar{c}_i = \frac{1}{n} \sum_{j=1}^n \left| PC_{ij} - \frac{(USL_{PC_i} + LSL_{PC_i})}{2} \right| \quad (18)$$

$$S_{C_i} = \frac{1}{n-1} \left(\sum_{j=1}^n \left| PC_{ij} - \frac{(USL_{PC_i} + LSL_{PC_i})}{2} \right|^2 - n \bar{c}_i^2 \right) \quad (19)$$

and t is the Student's t distribution.

Walter *et al.* [8] proposed the multivariate PCIs based on the eigenvalue problem and quadratic form. First, we can generalize the formula of the univariate PCI $C_p = (USL - LSL)/6s$ using the expression $\text{diag}((USL - LSL)/6) S_{X'X}^{-1} \text{diag}((USL - LSL)/6)$. Then, we can define the uncorrected multivariate PCI by

$$MC_p^{(B1)} = \min_{j=1,\dots,v} \left\{ \text{eigenvalues} \times \left[\text{diag} \left(\frac{USL - LSL}{6} \right) S_{X'X}^{-1} \times \text{diag} \left(\frac{USL - LSL}{6} \right) \right]^{1/2} \right\} \quad (20)$$

This formula compares the diagonal of a standardized tolerance region with the length of the longest space diagonal of the standardized variance matrix. Furthermore, a quadratic correction of the equation (20) is given by

$$MC_{pk}^{(B1)} = \frac{MC_p^{(B1)}}{D_B} \quad (21)$$

where $D_B = \sqrt{1 + (\bar{X} - T)^T (\sum \text{th})^{-1} (\bar{X} - T)}$ and $\sum \text{th} = \text{diag}((USL_j - LSL_j)/6) \times ((USL_j - LSL_j)/6)$.

The quadratic correction above does not consider the dependence between the product variables. That is, the tolerance region can be a circle or a sphere. The interpretation of this index is similar to the univariate index C_{pk} . They also proposed the multivariate PCIs

based on the eigenvalue problem (see the details in Walter *et al.* [8]).

Pearn *et al.* [9] provided the probability of producing a good product satisfying all its specifications. The process yield is defined as

$$p = \int_{[LSL, USL]} N_v(X|\mu, \Sigma) dX \quad (22)$$

Furthermore, they proposed a generalized process yield index $TS_{pk,PC}$, based on the index S_{pk} [13] and the PCA method which is similar to Wang and Du [7]. They also provided a lower confidence bound for the true process yield.

Discussion

These methods proposed by Chan *et al.* [2], Pearn *et al.* [3], Taam *et al.* [4], Shahriari *et al.* [6], Walter *et al.* [8], and Pearn *et al.* [9], respectively, must use the assumption of multivariate normality, while those proposed by Chen [5] and Wang and Du [7] do not require this assumption of multivariate normality. The tolerance regions of these methods using the assumption of multivariate normality are ellipsoidal except for Shahriari *et al.* [6]. On one hand, Chen [5] and Wang and Du [7] provided more flexible methods in assessing the capability for multivariate data. Wang *et al.* [14] presented a comparison of three methods by Tamm *et al.* [4], Shahriari *et al.* [6], and Chen [5]. In general, these proposed approaches all have their own reasonable points of view, but we still cannot obtain a consistent method of assessing the multivariate PCIs. Apparently, we should make an effort to study the relevant issues in the multivariate PCIs. Here, we give a simple summary for the multivariate PCIs (see Table 1).

Example

Let us consider an example of a device on an integrated circuit. The width (x_1) and thickness (x_2) are two important characteristics for a device on an integrated circuit to ensure good conductivity. The specifications for these two variables are (5, 6) (μm) and (0.6, 1.2) (μm), respectively. The targets of the specifications are (5.5, 0.9). From a sample of 30 observations, we have the sample mean vector and the sample covariance matrix which are $\bar{X} = \begin{bmatrix} 5.512 \\ 0.901 \end{bmatrix}$

Table 1 The summary of multivariate process capability indices

Authors	PCI	Distribution application	Tolerance form	Category
Chan <i>et al.</i> [2]	C_{pm}	Multivariate Normal	Elliptical	Ratio value
Pearn <i>et al.</i> [3]	${}_vC_{pm}, {}_vC_p$	Multivariate Normal	Elliptical	Ratio value
Taam <i>et al.</i> [4]	MC_{pm}, MC_p	Multivariate Normal	Elliptical	Ratio value
Chen [5]	MC_p	No specific	No specific	Process yield
Shahriari <i>et al.</i> [6]	$[C_{pM}, PV, LI]$	Multivariate Normal	Elliptical	Ratio value
Wang and Du [7]	MC_{pm}, MC_{pk}, MC_p	No specific	No specific	Ratio value
Walter <i>et al.</i> [8]	$MC_p^{(B1)}, MC_{pk}^{(B1)}$	Multivariate Normal	Elliptical	Ratio value
Pearn <i>et al.</i> [9]	$2\Phi(3TS_{pk;PC}) - 1$	Multivariate Normal	Elliptical	Process yield

Table 2 The results for example

Authors	Estimated values
Chan <i>et al.</i> [2]	$C_{pm} = 1.0157$
Taam <i>et al.</i> [4]	$MC_p = 2.9099, MC_{pm} = 2.9099/1.0166 = 2.8765$
Shahriari <i>et al.</i> [6]	$(C_{pM}, PV, LI) = (1.1899, 0.7250, 1)$
Wang and Du [7]	$MC_p = 1.1133, MC_{pk} = 1.091^{(a)}, MC_{pm} = 1.1110$
Walter <i>et al.</i> [8]	$MC_p^{(B1)} = 0.8733, MC_{pk}^{(B1)} = 0.8733/1.0063 = 0.8678$
Pearn <i>et al.</i> [9]	The estimated process yield is 0.9984

^(a)95% lower confidence bound: $MC_p = 0.8699, MC_{pk} = 0.8388$

and $S = \begin{bmatrix} 0.0257 & 0.0097 \\ 0.0097 & 0.0044 \end{bmatrix}$, respectively. Now we calculate the capability values for this case depending on several methods we introduce and we give a summary in Table 2. From Table 2, all capability indices are larger than 1 except the indices of Walter *et al.* [8]. This means that the variation of the process is small, the mean of the process is close to the center of specification and the mean of the process is around the target. Based on this result, we can conclude that this process is capable. By observing the spread of the 30 observations in the above figures, it is clear that this conclusion is reasonable. Here we get the estimated process yield 0.9984 by using the maple program. This means that the process produces high percentage of conforming products and implies the process is capable. Hence, the process should have high process capability values. According to the above process capability values calculated, we can infer that the estimated process yield is rational.

Conclusion

Often, a manufactured product is described in multiple characteristics. That is, manufactured items require values of several different characteristics

for adequate description of their quality. Each of those characteristics must satisfy certain specifications. The assessed quality of a product depends on the combined effects of these characteristics, rather than on their individual values.

Currently, the research of multivariate PCIs is still very sparse in comparison to the research of the univariate PCIs. Also, there is no consistency regarding a methodology for evaluating the process capability with multiple quality characteristics. In addition, it is very difficult to obtain the relevant statistical properties to make a more detailed inference for the multivariate PCIs. Thus, we realize that there are still critical difficulties in trying to assess the value of multivariate systems in terms of a single value. Clearly, further investigations in this field are needed.

Statistical Process Control, Multivariate

Introduction

Multivariate statistical process control (SPC) combines process control and process capability analysis. Although multivariate SPC was developed in the 1940s [1], its intensive use in industry started in the 1980s [2–5]. The emergence of computer-automated production systems and automated data collection systems equipped with data analysis technology had a significant impact on the use of multivariate SPC in industry. Such systems collect multivariate measurements rapidly, in a cost-effective way, and provide effective data analysis capabilities. Some examples include integration in production systems of process analytical techniques (PAT), three-dimensional coordinate measurement machines and vision systems based on cameras, and laser technology [6].

The oldest and fundamental multivariate SPC chart is the Hotelling T^2 chart that monitors the process mean and provides an out-of-control signal when the process mean shifts significantly from its normal behavior (see **Hotelling's T^2 ; Multivariate Control Charts Overview**). The Hotelling T^2 chart, plots the T^2 statistic also known as the *Mahalanobis distance*. The chart has an upper control limit (UCL) and points exceeding that limit are regarded as an out-of-control signal. The charted T^2 statistic is a function that reduces multivariate observations into a single value. This function includes the **covariance** matrix among its variables. Although the chart is powerful in detecting shifts in mean values, the lack of practical meaning of the T^2 statistic hinder its interpretation by engineers.

Recently, various methods have been developed to facilitate the proper interpretation of the T^2 signals [5, 7]. Some of these methods attempt to detect variables responsible for out-of-control signals on the chart. These methods are effective in uncovering the problem source, whenever the problem is caused by a subset of variables contributing significantly to the signal. The assumption that the problem sources affect only certain variables is not always valid and explains only a certain class of out-of-control signals. For the determination of patterns created by specific problem sources, one may use methods based on

in-depth process expertise. Once such patterns are identified, special charts can be designed for detecting their occurrences in the process. These charts track deviations in the variable means in specific directions or in the form of the T^2 statistic [8, 9].

The setup of a multivariate SPC chart consists of a process capability study [7, 10]. Following a process capability study, control limits and control procedures are determined. The process capability study period is sometimes referred to as *phase I*. The ongoing control using control limits determined in phase I is then called *phase II* [5].

The distinction between these two phases is important. Phase I analysis estimates parameters that will be used subsequently for ongoing monitoring of the process or phase II [11]. Phase I should use a relatively large sample to estimate the parameters and control limits used in phase II. For multivariate data analysis techniques and **multivariate capability indices**, see **Multivariate Analysis, Process Yield, and Multi-Vari Charts**.

In setting multivariate SPC charts, one meets several alternative scenarios derived from the characteristics of the reference sample and the appropriate control procedure. These include

1. internally derived targets
2. using an external reference sample
3. externally assigned targets
4. measurements units considered as batches.

In this section we cover techniques for multivariate SPC under these four scenarios. We then proceed to cover the step down and variable decomposition procedures and applications of multivariate statistical tolerance regions to SPC.

Internally Derived Targets

Internally derived targets are a typical scenario for process capability studies. This phase is further divided into two stages [12]. The first stage of phase I is *retrospective*, and historical data are used to estimate the relevant parameters. The second stage is *prospective* and the parameters estimated in the first stage are applied to a group of values and tested for accuracy. The parameters that must be estimated include the process mean vector, i.e., the *internally derived targets*, the process covariance matrix, and the control limit for the control chart.

2 Statistical Process Control, Multivariate

Consider a process capability study with a the base sample of size n of p -dimensional observations, $X_1, X_2, \dots, X_n$. When the data are grouped and k subgroups of observations of size m are being monitored, $n = km$, the covariance matrix estimator, S_p can be calculated as the pooled covariances of the subgroups [13]. In that case, for the j th subgroup, the Hotelling T^2 statistic is given by:

$$T^2 = m(\bar{X}_j - \bar{\bar{X}})' S_p^{-1} (\bar{X}_j - \bar{\bar{X}}) \quad (1)$$

where $\bar{X}_j$ is the mean of the j th subgroup, $\bar{\bar{X}}$ is the overall mean, and S_p^{-1} is the inverse of the pooled estimated covariance matrix. The UCL for this case is

$$UCL = \frac{p(k-1)(m-1)}{k(m-1) - p + 1} F_{p, k(m-1) - p + 1}^\alpha \quad (2)$$

When the data are ungrouped, and individual observations are analyzed, the estimation of the proper covariance matrix and control limits requires further consideration. Typically in this case, the covariance matrix is estimated from the pooled individual observations as $S = (1/n - 1) \sum_{i=1}^n (X_i - \bar{X})(X_i - \bar{X})'$, where $\bar{X}$ is the mean of the n observations. The corresponding T^2 statistic for the i th observation, $i = 1, \dots, n$ is given by $T^2 = (X_i - \bar{X})' S^{-1} (X_i - \bar{X})$.

In this case $(X_i - \bar{X})$ and S are not independently distributed and the appropriate upper control for T^2 is based on the beta distribution with

$$UCL = \frac{(n-1)^2}{n} B_{p/2, (n-p-1)/2}^{\alpha/2} \quad (3)$$

and

$$LCL = \frac{(n-1)^2}{n} B_{p/2, (n-p-1)/2}^{1-\alpha/2} \quad (4)$$

where $B_{p/2, (n-p-1)/2}^\alpha$ is the $100(1 - \alpha)$ th percentile of the beta distribution with $p/2$ and $(n - p - 1)$ as parameters. While theoretically the lower control limit (LCL) can be calculated as above, in most circumstances LCL is set to zero [14].

While control charts based on the T^2 and control values are commonly used, Sullivan and Woodall [12] found that the pooled individual observation estimator was relatively inaccurate in most of the tests. Using simulation, they evaluated several techniques to estimate the covariance matrix for monitoring individual data. Two techniques that incorporated a subgroup breakdown of the individual observations and an overlapping of the subgroups were found to perform particularly well. The overlapping technique,

in which observations were included in more than one subgroup, created a dependence of subgroups on each other and strengthened their statistical power to estimate the process covariance matrix and mean vector [12]. The use of such techniques is particularly relevant when the assumption of independence of the observations in the base sample is not necessarily valid. The resulting process covariance matrix and mean vector can then be used for setting the control limits. Once a UCL is set, the data of the reference sample can be evaluated for in-control characteristics. Points outside the UCL can be due to outliers or process instability. Gnanadesikan [15] and Fuchs and Kenett [7] present several techniques for identifying multivariate outliers.

Using an External Reference Sample

Consider again a process yielding assumed independent observations $X_1, X_2, \dots$ of a p -dimensional random variable $\mathbf{X}$, such as quality characteristics of a manufactured item or process measurements. Initially, when the process is “in control”, the observations follow a distribution F , with density f . We now assume that we have a “reference” (prerun) sample $X_1, \dots, X_n$ of F from an in-control period. To control the quality of the produced items or of the process, multivariate data is monitored for potential change in the distribution of $\mathbf{X}$, by sequentially collecting and analyzing the observations X_i . At some time $t = n + k$, k time units after n , the process may run out of control and the distribution of the X_i 's changes to G . Our aim is to detect, in phase II, the change in the distribution of subsequent observations X_{n+k} , $k \geq 1$, as quickly as possible, subject to a bound $\alpha \in (0, 1)$ on the probability of raising a false alarm at each time point $t = n + k$ (that is, the probability of erroneously deciding that the distribution of X_{n+k} is not F). The reference sample $X_1, \dots, X_n$ does not incorporate the observations X_{n+k} taken after the prerun stage, even if no alarm is raised for it, so the rule will be conditional only on the reference sample. As described below the structure of the reference sample can vary and we will later indicate how to handle other alternatives.

As an example, consider the measurements of the aluminum pins case study presented in [7]. The data consists of six recorded dimensions, per part. Data

Table 1 Data on six dimensions recorded on 30 parts used in process capability study (Phase I)

ID	Dimension 1	Dimension 2	Dimension 3	Dimension 4	Dimension 5	Dimension 6
1	9.99	9.97	9.96	14.97	49.89	60.02
2	9.96	9.96	9.95	14.94	49.84	60.02
3	9.97	9.96	9.95	14.95	49.85	60
4	10	9.99	9.99	14.99	49.89	60.06
5	10	9.99	9.99	14.99	49.91	60.09
6	9.99	9.99	9.98	14.99	49.91	60.08
7	10	9.99	9.99	14.98	49.91	60.08
8	10	9.99	9.99	14.99	49.89	60.09
9	9.96	9.95	9.95	14.95	50	60.15
10	9.99	9.98	9.98	14.99	49.86	60.06
11	10	9.99	9.98	14.99	49.94	60.08
12	10	9.99	9.99	14.99	49.92	60.05
13	9.97	9.96	9.96	14.96	49.9	60.02
14	9.97	9.96	9.96	14.96	49.91	60.02
15	9.97	9.97	9.96	14.97	49.9	60.01
16	9.97	9.97	9.96	14.97	49.89	60.04
17	9.98	9.97	9.96	14.96	50.01	60.13
18	9.98	9.97	9.97	14.96	49.93	60.06
19	9.98	9.98	9.97	14.98	49.93	60.02
20	9.98	9.97	9.97	14.97	49.94	60.06
21	9.98	9.97	9.97	14.97	49.93	60.06
22	9.98	9.97	9.97	14.97	49.91	60.02
23	9.98	9.97	9.96	14.98	49.92	60.06
24	10	9.99	9.98	14.98	49.88	60
25	9.99	9.99	9.99	14.98	49.91	60.04
26	10	9.99	9.99	14.99	49.85	60.01
27	10	10	9.99	14.99	49.91	60.05
28	10	9.99	9.99	15	49.92	60.04
29	10	9.99	9.99	14.99	49.89	60.01
30	10	10	9.99	14.99	49.88	60

from 30 parts manufactured in an “in-control” base sample is presented in Table 1.

The mean vector of the base sample is $\bar{X}$ and the estimated covariance matrix is S . For the data above:

$$\bar{X}' = (9.99, 9.98, 9.97, 14.98, 49.91, 60.05) \quad (5)$$

The inverse covariance matrix is

$$S^{-1} = \begin{vmatrix} 53192.3 & -22792.3 & -17079.7 & -9343.4 & 145 & -545.3 \\ & 66325.1 & -28341.1 & -10877.9 & 182 & 1522.8 \\ & & 50553.9 & -6467.9 & 853 & -1465.1 \\ & & & 25745.6 & -527.5 & 148.6 \\ & & & & 1622.3 & -1156 \\ & & & & & 1577.6 \end{vmatrix} \quad (6)$$

For each future observation $\mathbf{Y}$ of dimension $p = 6$, we compute the T^2 statistic as

$$T^2 = (\mathbf{Y} - \bar{\mathbf{X}})' S^{-1} (\mathbf{Y} - \bar{\mathbf{X}}) \quad (7)$$

Under the null hypothesis, the T^2 statistic has a $((n-1)p/(n-p))F_{p,n-p}$ distribution with $n = 30$ and $p = 6$.

Figure 1 T^2 value chart with setup values determined by the first 30 observations. Observation 44 is the first out-of-control signal

Accordingly, the 0.95 UCL for T^2 is $UCL = ((n-1)p/(n-p))F_{p,n-p}^{.95} = 16.35$.

Figure 1 presents the values of T^2 using the mean and covariance of the first 30 samples. The base sample is indeed identified as “in control” with no T^2 value exceeding the UCL. As the production process continued producing aluminum pins some products signaled an out-of-control condition. For example, the T^2 value for the 44th observation (10, 10, 10, 15, 49.93, 59.98) is 20.167, and exceeds the UCL.

When the data in phase II are grouped, and the reference sample from historical data includes k subgroups of observations of size m , $n = km$, with the covariance matrix estimator S_p calculated as the pooled covariances of the subgroups, the T^2 for a new subgroup of size m with mean $\bar{Y}$ is given by $T^2 = m(\bar{Y} - \bar{\bar{X}})'S_p^{-1}(\bar{Y} - \bar{\bar{X}})$, and the UCL is given by $UCL = (p(k+1)(m-1)/k(m-1) - p + 1)F_{p,k(m-1)-p+1}^\alpha$. Furthermore, if in phase I, l subgroups were outside the control limits and assignable causes were determined, those subgroups are omitted from the computation of $\bar{\bar{X}}$ and S_p^{-1} , and the control limits for this case are $UCL = (p(k-l+1)(m-1)/(k-l)(m-1) - p + 1)F_{p,(k-l)(m-1)-p+1}^\alpha$. The T^2 control charts constructed in phase I and used both in phase I and in phase II are the multivariate equivalent of the Shewhart control chart. Those charts as well as some

more advanced ones simplify the calculations down to single-number criteria and produce a desired Type I error or in-control run length. More advanced charts like the multivariate cumulative sum (MCUSUM) and the multivariate exponentially weighted moving average (MEWMA) produce charts, which, similar to their univariate equivalent, are more sensitive to small deviations from control.

While we focused on the reference sample provided by phase I of the multivariate process control, other possibilities can occur as well. In principle, the reference in-control sample can also originate from historical data which are not part of the current process control. In this case, the statistical analysis will be the same but this situation has to be treated with precaution since both the control limits and the possible correlations between observations may be shifted.

Externally Assigned Targets

If all parameters of the underlying multivariate distribution are known and externally assigned, the T^2 value for a single multivariate observation of dimension p is computed as:

$$T^2 = (\mathbf{Y} - \boldsymbol{\mu})' \boldsymbol{\Sigma}^{-1} (\mathbf{Y} - \boldsymbol{\mu}) \quad (8)$$

where $\boldsymbol{\mu}$ and $\boldsymbol{\Sigma}$ are the expected value and covariance matrix, respectively.

The probability distribution of the T^2 statistic is a χ^2 distribution with p **degrees of freedom**. Accordingly, the 0.95 UCL for T^2 is $UCL = \chi^2(0.05, p)$.

When the data are grouped in subgroups of size m , and both μ and Σ are known, the T^2 value of the mean vector $\bar{Y}$ is $T^2 = m(\bar{Y} - \mu)' \Sigma^{-1} (\bar{Y} - \mu)$ with the same UCL as above.

If only the expected value of the underlying multivariate distribution, μ , is known and externally assigned, the covariance matrix has to be estimated from the tested sample. The T^2 value for a single multivariate observation of dimension p is computed as

$T^2 = (\mathbf{Y} - \mu)' S^{-1} (\mathbf{Y} - \mu)$, where μ is the expected value and S is the estimate of the covariance matrix Σ , estimated either as the pooled contribution of the individual observations, i.e. $S = (1/n - 1) \sum_{i=1}^n (X_i - \bar{X})(X_i - \bar{X})'$, or by one of the methods suggested by Sullivan and Woodall [12], which account for possible lack of independence between observations.

In this case, the 0.95 UCL for T^2 is $UCL = (p(n - 1)/n(n - p)) F_{p, n-p}^{0.95}$.

When the tested observations are grouped, the mean vector of a subgroups with m observations (a rational sample) will have the same expected value as the individual observations, μ , and a covariance matrix Σ/m . The covariance matrix Σ can be estimated by S or as S_p obtained by pooling the covariances of the k subgroups.

When Σ is estimated by S , the T^2 value of the mean vector $\bar{Y}$ of m tested observation is $T^2 = m(\bar{Y} - \mu)' S^{-1} (\bar{Y} - \mu)$ and the 0.95 UCL is $UCL = (p(m - 1)/m - p) F_{p, m-p}^{0.95}$. When Σ is estimated by S_p , the 0.95 UCL of $T^2 = m(\bar{Y} - \mu)' S_p^{-1} (\bar{Y} - \mu)$ is $UCL = (pk(m - 1)/k(m - 1) - p + 1) F_{p, k(m-1)-p+1}^{0.95}$.

Measurements Units Considered as Batches

In many situations, the production is organized in batches. In those cases, the quality-control process can be performed in one of the two modes, either at the completion of the batch or sequentially, in a curtailed inspection, aiming at reaching a decision as soon as possible. Whenever the quality-control method determines that the decision is to be reached at the completion of the process, the two possible outcomes are (a) determine the production process

to be in statistical control and accept the batch or (b) stop the production flow because of a signal that the process is out of control. On the other hand, in a curtailed inspection, based on a statistical stopping rule, the results from the first few items tested may suffice to stop the process prior to the batch completion.

Let us consider a batch of size n , with the tested items $\mathbf{Y}_1, \dots, \mathbf{Y}_n$. The curtailed inspection tests the items sequentially. Assume that the targets are specified, either externally assigned, or from a reference sample or batch. With respect to those targets, let $V_i = 1$ if the T^2 of the ordered i th observation exceeds the critical value κ and $V_i = 0$, otherwise. For the i th observation, the process is considered to be in control if for a prespecified P , say $P = 0.95$, $\Pr(V_i = 0) \geq P$. Obviously, the inspection will be curtailed only at an observation i for which $V_i = 1$ (not necessarily the first).

Let $N(g) = \sum_{i=1}^g V_i$ be the number of rejection up to the g th tested item. For each number of individual rejections U (out of n), $R(U)$ denotes the minimal number of observations allowed up to the U th rejection, without rejecting the overall null hypothesis. Thus, for each U , $R(U)$ is the minimal integer value such that under the null hypothesis, $\Pr\left(\sum_{i=1}^{R(U)} V_i \leq U\right) \geq \alpha$. For fixed U , the random variable $\sum_{i=1}^U V_i$ has a negative binomial distribution, and we can compute $R(N(g))$ from the inverse of the negative binomial distribution. For example when $n = 13$, $P = 0.95$, and $\alpha = 0.01$, the null hypothesis is rejected if the second rejection occurred at or before the third observation, or if the third rejection occurred at or before the ninth observation, and so on (see [7]).

Variable Decomposition and Monitoring Indices

The batched data are naturally grouped, but even if quality control is performed on individual items, grouping the data into rational consequent subgroups may yield relevant information within subgroups variability in addition to the deviations from targets.

In the j th subgroup (or batch) of size n_j the individual T_{ij}^2 values, $i = 1, \dots, n_j$ are given by $T_{ij}^2 = (\mathbf{Y}_{ij} - \theta)' G^{-1} (\mathbf{Y}_{ij} - \theta)$. When the targets are externally assigned then $\theta = \mu$. If the covariance matrix is also externally assigned then $G = \Sigma$, otherwise G is

the covariance matrix estimated either from the tested or from the reference sample. In the case of targets derived from an external reference sample $\theta = \mathbf{m}$ and $G = S$, where $\mathbf{m}$ and S are the mean and the covariance matrix of a reference sample of size n . Within the j th subgroup, let us denote the mean of the subgroup observations by $\bar{Y}_j$ and the mean of the target values in the j th subgroup by θ_j .

The sum of the individual T_{ij}^2 values, $T_{0j}^2 = \sum_{i=1}^n T_{ij}^2$ can be decomposed into two measurements of variability, one representing the deviation of the subgroup mean from the multivariate target denoted by T_{Mj}^2 , and the other measuring the internal variability within the subgroup, denoted by T_{Dj}^2 . The deviation of the subgroup mean from the multivariate target is estimated by $T_{Mj}^2 = (\bar{Y}_j - \theta_j)' G^{-1} (\bar{Y}_j - \theta_j)$, while the internal variability within the subgroup is estimated by $T_{Dj}^2 = (\mathbf{Y}_{ij} - \bar{Y}_j)' G^{-1} (\mathbf{Y}_{ij} - \bar{Y}_j)$, with $T_{0j}^2 = T_{Mj}^2 + T_{Dj}^2$.

Since asymptotically, T_{Mj}^2 and T_{Dj}^2 have a χ^2 distribution with p and $(n-1)p$ degrees of freedom, respectively, one can further compute two indices, I_1 and I_2 , to determine whether the overall variability is mainly due to the distances between the means of the tested subgroup from targets or to the within subgroup variability. The indices are relative ratios of the normalized versions of the two components of T_{0j}^2 , i.e., $I_1 = I_1^*/(I_1^* + I_2^*)$ and $I_2 = I_2^*/(I_1^* + I_2^*)$, where $I_1^* = T_{Mj}^2/p$ and $I_2^* = T_{Dj}^2/[(n-1)p]$. We can express the indices in terms of the original T^2 statistics as, $I_1 = (n-1)T_{Mj}^2/[(n-1)T_{Mj}^2 + T_{Dj}^2]$ and $I_2 = T_{Dj}^2/[(n-1)T_{Mj}^2 + T_{Dj}^2]$. Tracking these indices provides powerful monitoring capabilities. For more details and examples see [7].

Multivariate Tolerance Regions

An alternative approach to design a multivariate SPC scheme is to use tolerance regions as a basis for decision making. Tolerance regions provide inferential capabilities on **percentiles** of distributions. A specific value of a variable is a tolerance limit for a proportion p , at a specific confidence level, for example 95%. If we set control limits of a univariate control chart using tolerance limits for the 0.013 and 0.987 proportion, at the 95% confidence level, we obtain UCLs and LCLs that are different from the 3σ Shewhart control limits. The advantage of fusing tolerance region is that they are easily extendable

to several dimensions with the concept of proportion and confidence level remaining unchanged.

Let $\mathbf{X}_1, \dots, \mathbf{X}_n$ be a sample of n independent and identically distributed observations from a multivariate **normal distribution** of dimension p with mean μ and covariance matrix Σ . In the quality-control area we use a sample $(\mathbf{X}_1, \dots, \mathbf{X}_n)$ as a reference sample for setting the standards to which each new observation is compared.

When using a tolerance region as a standard, it is necessary to construct from $(\mathbf{X}_1, \dots, \mathbf{X}_n)$ a region about which we can assert with probability δ that the proportion of the individuals in the population contained in that region is greater than or equal to Γ . Each new observation is tested to determine whether it belongs to that region.

Let X_{ih} ($i = 1, 2, \dots, p$) be the value of the i th attribute for the h th observation ($h = 1, 2, \dots, n$) and S the empirical covariance matrix with elements s_{ij} :

$$s_{ij} = \sum_{h=1}^n \frac{(X_{ih} - \bar{X}_i)(X_{jh} - \bar{X}_j)}{(n-1)} \quad (9)$$

The means $\bar{X}_i$ and $\bar{X}_j$ are the i th and j th elements, respectively, of the sample mean vector $\bar{\mathbf{X}} = (\bar{X}_1, \dots, \bar{X}_p)$. It has been shown [16] that if we ignore terms of order two in $(1/n)$ the tolerance region can be defined by the $\mathbf{X}$ vectors satisfying the inequality

$$(\mathbf{X} - \bar{\mathbf{X}})' \mathbf{S}^{-1} (\mathbf{X} - \bar{\mathbf{X}}) \leq k \quad (10)$$

where k is a function of the prespecified (Γ, δ) and of the dimensionality of the problem (p). (The left-hand side of equation (10) is the Mahalanobis distance.)

The critical value k is defined as follows: Let $g(\phi, f, m)$ be the ϕ th percentile of the noncentral χ^2 distribution with m degrees of freedom and noncentrality parameter f . As a special case, $g(\phi, 0, m)$ is the ϕ th percentile of the central χ^2 distribution.

$$Pr(\chi_m^2 \leq g(\phi, 0, m)) = \phi \quad (11)$$

The critical value k (see John [16]) is given by

$$k = \frac{g(\Gamma, p/2n, p)(n-1)p}{g(1-\delta, 0, (n-1)p)} \quad (12)$$

with $p/2n$ being the noncentrality parameter of the χ^2 distribution.

Other approximations have been provided by Krishnamoorthy and Mathew [17]. The tolerance limits approach to process control, as an alternative to the classical control limits extending the basic Shewhart chart, is slowly gaining popularity. Parametric and nonparametric multivariate tolerance regions have been investigated by Di Bucchianico *et al.* [18] and Baillo and Cuevas [19].

Several aspects of multivariate SPC have been covered in this entry. In particular we carefully distinguished between alternative scenarios for establishing multivariate SPC including internal and external reference samples and data in batches or considered individually.

Other Multivariate Charts

In the multivariate equivalent of the Shewhart chart, the determination of the state of statistical control is based only on the current observation vector. As their univariate counterparts, the multivariate charts that plot statistics based on weighted sequences of previous observations are in general more sensitive to small deviations from control.

Alwan [20] and Crosier [21] suggested MCUSUMs charts of T^2 and T , respectively, as multivariate extensions of univariate cumulative sum (CUSUM) (*see Cumulative Sum (CUSUM) Chart*). Woodall and Ncube [22] considered a procedure based on individual CUSUM of the variables in X with a signal triggered if any of the p CUSUMs exceeds its control limit. The approach has the advantage of better interpretability than procedures based on T . However, when the variables are highly correlated, procedures that capitalize on the correlation between variables will provide improved performance.

The MEWMA chart [23], which is an extension of the univariate version of exponentially weighted moving average (EWMA), plots the statistics $T_i^2 = Z_i' \sum_{j=1}^i Z_j$, where $Z_i = \lambda X_i + (1 - \lambda)Z_{i-1}$, $\sum_{j=1}^i Z_j$ is the covariance matrix, and λ is the EWMA weighting matrix. By using various weights for each variable, the investigator can perform a sensitivity analysis. Prabhu and Runger [24] show that the choice of λ does not dramatically affect in-control run length. When all the variables are assigned equal weights, the chart is directionally invariant as are the univariate versions of the CUSUM and EWMA. On the other

hand, by using direction analysis on MCUSUM and MEWMA, one can determine shifts of particular variables along their respective axes, and manipulate specific variables to “aim” them in a particular direction [25]. The results of Runger and Prabhu [26] concur with Lowry *et al.* [23] that in general the MEWMA is more effective in detecting mean shifts than **Hotelling’s T^2** chart.

Hawkins [27] proposed to track a vector Z , derived from scaled **residuals** from the regression of each variable on all others. He shows how T^2 can be determined as a sum of p weighted Z_i where the weights are a scaled distance of X_i from the mean. He then considers an individual-chart approach in which each Z_i is monitored separately and a group-chart approach in which a single composite measure computed from the p charts is used to signal an out-of-control condition. These proposals have been shown to perform better than the proposals mentioned in the previous paragraph in shifts of single and pairs of components of X .

Cheng and Thaga [28] propose a multivariate control chart referred to as the *Max-MCUSUM chart* that is capable of simultaneously detecting shifts in both mean vector and covariance matrix of a multivariate process. The chart is based on standardizing the sample mean vectors and covariance matrices and finding the sampling distribution of the standardized values.

Li and Johnson [29] recently introduced a new MCUSUM scheme whose components are the difference between the univariate CUSUM statistic for detecting an increase and that for detecting a decrease. The procedure also applies when monitoring principal components. They also suggest another procedure where, at each new observation, the results for the two most active components are graphed with the two components being selected to have the largest value of the appropriate bivariate CUSUM statistic.

When the assumption of independence between successive observations does not hold, more complex techniques are required. A popular approach is to model the **autocorrelation** in the data and apply standard procedures for independent observations to the residual data [30–32]. Such modeling can involve multivariate dynamic linear model (DLM) or classic **time series** models, such as autoregressive integrated moving average (ARIMA) models. The classic time series models are static in nature implicitly assuming that unknown model parameters remain constant as

time passes while the DLM techniques allow the parameters to be updated.

Yeh *et al.* [33] provide a comprehensive review of **multivariate control charts** for monitoring a covariance matrix and conclude with an appeal for future investigations to compare existing charts in a systematic, organized, and thorough manner. An additional family of models for multivariate process control includes Bayesian tracking procedures such as extensions of the at most one change (AMOC) models developed in [34].

Process Capability Indices, Bayesian Estimation of

Process Capability Indices

The process capability index, C_p , relates process variation to customer requirements in the form of a ratio

$$C_p = \frac{USL - LSL}{6\sigma} \quad (1)$$

where the difference between the upper specification limit (USL) and the lower specification limit (LSL) provides a measure of allowable process spread and 6σ , σ^2 being the process variance, a measure of actual process spread.

The failure of C_p to consider a target value resulted in the development of several indices. Those indices that assume the target (T) to be the midpoint of the upper and lower specification limits include

$$C_{pu} = \frac{USL - \mu}{3\sigma} \quad (2)$$

$$C_{pl} = \frac{\mu - LSL}{3\sigma} \quad (3)$$

$$C_{pk} = \min(C_{pl}, C_{pu}) \quad (4)$$

$$C_{pm} = \frac{USL - LSL}{6\sqrt{\sigma^2 + (\mu - T)^2}} \quad (5)$$

and

$$C_{pk} = (1 - k)C_p \quad (6)$$

where μ denotes the process mean, $k = 2|T - \mu| / (USL - LSL)$, $0 \leq k \leq 1$ and $LSL < \mu < USL$. The two definitions of C_{pk} are equivalent when $0 \leq k \leq 1$.

Generalized versions of these indices, that do not assume T to be the midpoint of the specification limits, include

$$C_{pu}^* = \frac{USL - T}{3\sigma} \left(1 - \frac{|T - \mu|}{USL - T} \right) \quad (7)$$

$$C_{pl}^* = \frac{T - LSL}{3\sigma} \left(1 - \frac{|T - \mu|}{T - LSL} \right) \quad (8)$$

$$C_{pk}^* = \min(C_{pl}^*, C_{pu}^*) \quad (9)$$

and

$$C_{pm}^* = \frac{\min[USL - T, T - LSL]}{3\sqrt{\sigma^2 + (\mu - T)^2}} \quad (10)$$

A hybrid of C_{pk}^* and C_{pm}^* is defined to be

$$C_{pmk} = \frac{\min[USL - \mu, \mu - LSL]}{3\sqrt{\sigma^2 + (\mu - T)^2}} \quad (11)$$

As all of these indices use a function of σ as a measure of actual process spread in their determination of process capability and, in practice, are translated into parts per million nonconforming, none should be used when the characteristic under investigation is not normally distributed. To illustrate, suppose that precisely 99.73% of the process measurements fall within the specification limits (i.e., a **process yield** of 2700 ppm) and the process is centered at the target. The values of C_p (as well as C_{pl} , C_{pu} , C_{pk} , C_{pm} , and C_{pmk}) are 0.5766, 0.7954, 1.0000, 1.2210, and 1.4030 when the measurements arise from a uniform, triangular, normal, logistic, and double exponential distribution respectively, yet the process yields are identical. Under these circumstances, the assumption that the underlying process is normally distributed is critical to both sampling results and parameter values.

A Bayesian Approach

The general Bayesian approach assumes the parameter(s) to be stochastic and uses sampling results to adjust an assumed prior distribution to develop a posterior distribution for the associated parameter(s). In the case of process capability indices, and following the assumption that the observations must arise from a **normal distribution**, the likelihood function for a sample of size n is

$$L(\mu, \sigma^2) = (2\pi\sigma^2)^{-n/2} e^{-\sum_{i=1}^n (x_i - \mu)^2 / (2\sigma^2)} \quad (12)$$

The noninformative prior density function

$$h(\mu, \sigma^2) = 1/\sigma \quad -\infty < \mu < \infty, \quad 0 < \sigma < \infty \quad (13)$$

results in the posterior distribution

$$f(\sigma | x_1, x_2, x_3, \dots, x_n)$$

2 Process Capability Indices, Bayesian Estimation of

$$= \frac{2}{\Gamma[(n-1)/2]} \left(\frac{(n-1)s^2}{2} \right)^{\frac{n-1}{2}} \sigma^{-n} e^{-\frac{(n-1)s^2}{2\sigma^2}} \quad (14)$$

where $s^2 = \sum_{i=1}^n (x_i - \bar{x})^2 / (n-1)$ and $\bar{x} = \sum_{i=1}^n x_i / n$. As each of the process capability indices is a function of the process parameters μ and σ , and judged based upon a value (e.g., $C_p > 1$) this allows equation (14) to be written as

$$\Pr(C_p > c | x_1, x_2, x_3, \dots, x_n) \quad (15)$$

In the case of C_p , Cheng and Spiring [1] rewrote equation (15)

$$\begin{aligned} \Pr(C_p > c | x_1, x_2, x_3, \dots, x_n) &= \Pr\left(\sigma < \left(\frac{USL - LSL}{6c}\right) | x_1, x_2, x_3, \dots, x_n\right) \\ &= \int_0^{(USL-LSL)/(6c)} f(\sigma | x_1, x_2, \dots, x_n) d\sigma \\ &= \int_0^{(USL-LSL)/(6c)} \frac{2}{\Gamma[(n-1)/2]} \\ &\quad \times \left(\frac{(n-1)s^2}{2}\right)^{\frac{n-1}{2}} \sigma^{-n} e^{-\frac{(n-1)s^2}{2\sigma^2}} d\sigma \quad (16) \end{aligned}$$

resulting in a credible interval that depends upon n, s^2, USL, LSL and c .

Program Cp: Mathematica v5.2 Code for determining $\Pr(C_p > c | x_1, x_2, x_3, \dots, x_n)$

```
In[1]: n:= ;
s2:= ;
specdiff:= ;
c:= ;
N[Integrate[(((2/Evaluate[Gamma
[(n-1)/2]]((n-1)s2/2)^(n-1/2))(x^(-n))
Exp[-((n-1)s2/2)/(x^2)]), {x,0, (specdiff/(6c))}]]]
```

The user must enter: **n** the sample size, **s2** the sample variance, **specdiff** = $(USL - LSL)$, and **c** the desired level of C_p .

Pearn and Wu [2] extended the credible interval approach for C_p to the case where $\hat{C}_p^*$ is essentially a pooled estimate of C_p based upon a series (m) of repeated samples (n). Minimum values for $\hat{C}_p^*$

have been developed for $m = 2(2)10, n = 10(5)30$, and $p = 0.95, 0.975, 0.99$ providing a Bayesian alternative to the capability chart developed in [3].

In the case of C_{pm} and the noninformative prior distribution defined in equation (13), the conditional distribution of equation (14) becomes

$$\begin{aligned} f(\sigma' | x_1, x_2, x_3, \dots, x_n) &= \frac{2\sigma'}{\Gamma[n/2]} \left(\frac{(n-1)s^2 + n(\bar{x} - \mu)^2}{2} \right)^{\frac{n}{2}} \\ &\quad \times (\sigma'^2 - (\mu - T)^2)^{-\left(\frac{n}{2}+1\right)} \\ &\quad \times e^{\frac{(n-1)s^2 + n(\bar{x} - \mu)^2}{-2(\sigma'^2 - (\mu - T)^2)}} \quad (17) \end{aligned}$$

where $\sigma'^2 = \sigma^2 + (\mu - T)^2$ and $(\mu - T)^2 < \sigma'^2 < \infty$. The resulting credible interval depends upon $n, x, s^2, USL, LSL, T, \mu$ and c and is of the form [4]

$$\begin{aligned} \Pr(C_{pm} > c | x_1, x_2, x_3, \dots, x_n) &= \int_0^{(USL-LSL)/(6c)} f(\sigma' | x_1, x_2, \dots, x_n) d\sigma' \\ &= \int_0^{(USL-LSL)/(6c)} \frac{2\sigma'}{\Gamma[n/2]} \\ &\quad \times \left(\frac{(n-1)s^2 + n(\bar{x} - \mu)^2}{2} \right)^{\frac{n}{2}} \\ &\quad \times (\sigma'^2 - (\mu - T)^2)^{-\left(\frac{n}{2}+1\right)} e^{\frac{(n-1)s^2 + n(\bar{x} - \mu)^2}{-2(\sigma'^2 - (\mu - T)^2)}} d\sigma' \quad (18) \end{aligned}$$

Program Cpm: Mathematica v5.2 Code for determining $\Pr(C_{pm} > c | x_1, x_2, x_3, \dots, x_n)$

```
In[1]: n:= ;
s2:= ;
mu:= ;
T:= ;
xbar:= ;
specdiff:= ;
c:= ;
Integrate[(2x/Evaluate[Gamma[n/2]]]
(((n-1)s2+n(xbar-mu)^2)/2)^(n/2)(x^2-
(mu-T)^2)^(-(n/2+1)) Exp[(((n-1)s2+n
(xbar-mu)^2)/(-2((x^2)-(mu-T)^2))],
{x,0,(specdiff/(6c))}]]]
```

The user must enter: **n** the sample size, **s2** the sample variance, **mu** the population average, **T** the target value, **xbar** = the sample average, **specdiff** = ($USL - LSL$), and **c** the desired level of Cpm .

In the case of Cpk , Shiau *et al.* [5] used the same approach to develop a credible interval restricted to the case where $m = (USL + LSL)/2$ by considering

$$\begin{aligned} \Pr(Cpk > c | x_1, x_2, x_3, \dots, x_n) \\ = \Pr\left(\sigma < \left(\frac{USL - LSL}{6c}\right) \middle| x_1, x_2, x_3, \dots, x_n\right) \end{aligned} \quad (19)$$

which for the posterior distribution defined in equation (14) becomes

$$\begin{aligned} \Pr(Cpk > c | x_1, x_2, x_3, \dots, x_n) \\ = \int_0^{(USL-LSL)/(6c)} f(\sigma | x_1, x_2, \dots, x_n) d\sigma \\ = \int_0^{(USL-LSL)/(6c)} \frac{2}{\Gamma[n/2]} \left(\frac{ns'^2}{2}\right)^{\frac{n}{2}} \\ \times \sigma^{-(n+1)} e^{-\frac{ns'^2}{2\sigma^2}} d\sigma \end{aligned} \quad (20)$$

where $s'^2 = \sum_{i=1}^n ((x_i - m)^2/n)$, resulting in a credible interval that depends upon n, s'^2, USL, LSL and c . The authors further simplify equation (20) to get

$$\begin{aligned} \Pr(Cpk > c | x_1, x_2, x_3, \dots, x_n) \\ = \int_b^\infty \frac{1}{\Gamma[n/2]} y^{(n/2)-1} e^{-y} dy \end{aligned} \quad (21)$$

for $b = n/2 (c/\hat{C}pk)^2$.

Program Cpk: Mathematica v5.2 Code for determining $\Pr(Cpk > c | x_1, x_2, x_3, \dots, x_n)$

```
In[1]: n:= ;
      cpkh:= ;
      c:= ;
      1-Integrate[(1/Evaluate[Gamma[n/2]])
      (y^((n/2)-1))
      Exp[-y],{y,0,(n/2)(c/cpkh)^2}]
```

The user must enter: **n** the sample size, **cpkh** = $(USL - LSL)/(6s')$, and **c** the desired level of Cpk .

In the case of Cpm^* , Lin *et al.* [6] developed a credible interval, $\Pr(Cpm^* > c | x_1, x_2, x_3, \dots, x_n) = p$, of the form

$$p = \begin{cases} \left\{ \int_0^{t^*} \frac{\Phi(b_1(y) + b_U^*(y)) - \Phi(b_1(y) - b_L^*(y))}{\gamma^\alpha y^{\alpha+1} \Gamma(\alpha)} \exp\left(-\frac{1}{\gamma y}\right) dy \right\} & \text{for } \bar{x} < T \\ \left\{ \int_0^{t^*} \frac{\Phi(b_1(y) + b_U^*(y)) - \Phi(b_1(y) - b_L^*(y))}{\gamma^\alpha y^{\alpha+1} \Gamma(\alpha)} \exp\left(-\frac{1}{\gamma y}\right) dy \right\} & \text{for } \bar{x} > T \end{cases} \quad (22)$$

where $t^* = 2[\min[USL - T, T - LSL]]/(2c)$
 $\times [(n-1)s^2 + n(\bar{x} - T)^2]^{-1}$,

Φ is the cumulative distribution function of the $N(0, 1)$,

$$b_1(y) = \left[(2/y)(1 - (1/(1 + ((n(\bar{x} - T)^2)/((n-1)s^2)))) \right]^{0.5},$$

$$\begin{aligned} b_U^*(y) &= [2(USL - T)/(USL - LSL)] \\ &\times [n((2(\min[USL - T, T - LSL])/(3c))^2 \\ &\times ((n-1)s^2 + n(\bar{x} - T)^2)^{-1})/y - 1]^{0.5}, \\ \gamma^2 &= (\bar{x} - T)^2/s^2, \end{aligned}$$

$$b_2(y) = [n((2\hat{C}pm^2/nyc^2) - 1)]^{0.5}, \text{ and}$$

$$\begin{aligned} b_L^*(y) &= [2(T - LSL)/(USL - LSL)] \\ &\times [n((2(\min[USL - T, T - LSL])/(3c))^2 \\ &\times ((n-1)s^2 + n(\bar{x} - T)^2)^{-1})/y - 1]^{0.5}, \end{aligned}$$

resulting in an interval that depends upon n, s^2, γ, USL, LSL and c .

The authors indicate that although equation (22) reduces to

$$p = \left\{ \int_0^{t^*} \frac{\Phi(b_1(y) + b_2(y)) - \Phi(b_1(y) - b_2(y))}{\gamma^\alpha y^{\alpha+1} \Gamma(\alpha)} \times \exp\left(-\frac{1}{\gamma y}\right) dy \right\} \quad (23)$$

4 Process Capability Indices, Bayesian Estimation of

Table 1 Process specifications and summaries

1.06	0.6926	1.06	0.7279	1.06	0.6929

^(a)From **Program Cp**

^(b)From **Program Cpm** for $\mu = T$

^(c)From **Program Cpk** for $m = (USL + LSL)/2$

where $t = 2\hat{C}_{pm}^2/(nc^2)$ when T is the midpoint of the specification limits, and the equivalent of equation (18) when $m = (USL + LSL)/2$, equation (22), is “complicated and computationally inefficient”.

Extension of the credible interval approach to C_{pmk} proves to be a difficult problem mathematically. Pearn and Lin [7] have examined some properties of C_{pmk} from a Bayesian estimation perspective.

Example

Braverman [8] discussed an example from a **quality control** department that wanted to assess the capability of a shaft manufacturing process. The shaft specifications were $USL = 2.15$ and $LSL = 2.01$ with $T = 2.08$. A random sample of 50 shafts was selected and measured with the following results (see Table 1)

Using the above **Mathematica** programs for C_p , C_{pm} , and C_{pk} , the associated Bayesian credible interval probabilities are listed in Table 2 suggesting that the probability that the process is deemed capable given the sampling results is approximately 0.7 for each of C_p , C_{pm} , and C_{pk} .

Comments

The amount of material associated with the Bayesian approach for assessing process capability represents a small portion of the work in the area of drawing

inferences regarding a process capability. A list of additional related manuscripts that deal with specific situations has been included. Much like the general development, the evolution of Bayesian inference in the area of process capability assessment appears to be dominated by academic interests and has had little practitioner input.

FRED SPIRING AND SMILEY CHENG

Process Capability Indices, Comparison of

Measuring Process Capability

Historically process capability was synonymous with process variation and expressed as either 6σ or the population range. Neither of these measures consider customer requirements nor permit general comparisons among processes as both measures are unit dependent. Juran [1] suggests that Japanese companies have initiated the use of process capability indices by relating process variation to customer requirements in the form of the ratio

$$C_p = \frac{USL - LSL}{6\sigma} \quad (1)$$

where the difference between the upper specification limit (USL) and the lower specification limit (LSL) provides a measure of allowable process spread (i.e., customer requirements) and 6σ , σ^2 being the process variance, a measure of actual process spread (i.e., process performance). Bissell [2] suggests that the British Standards Institution proposed an analogous measure referred to as the relative precision index, which was withdrawn and replaced by C_p in 1942.

Incorporating customer specification limits into the assessment of process capability results in a more meaningful measure that fosters comparisons across all types of processes. However C_p uses only the customer's USL and LSL in its assessment and fails to consider a target (or nominal) value. The three processes depicted in Figure 1 have identical values of σ^2 and therefore identical values of C_p . However, processes 2 and 3 deviate from the target (T), and additional work and/or costs due to these departures may be incurred. As a result processes 2 and 3 are considered less capable of meeting customer requirements than process 1.

Processes with small variability, but poor proximity to the target, have sparked the derivation of several indices that incorporate targets into their assessment. The most common of these measures assume the target (T) to be the midpoint of the specification limits and include

$$C_{pu} = \frac{USL - \mu}{3\sigma} \quad (2)$$

Figure 1 Three processes with identical values of C_p

$$C_{pl} = \frac{\mu - LSL}{3\sigma} \quad (3)$$

$$C_{pk} = \min(C_{pl}, C_{pu}) \quad (4)$$

$$C_{pm} = \frac{USL - LSL}{6\sqrt{\sigma^2 + (\mu - T)^2}} \quad (5)$$

and

$$C_{pk} = (1 - k)C_p \quad (6)$$

where μ is the process mean, $k = \frac{2|T - \mu|}{USL - LSL}$, $0 \leq k \leq 1$ and $LSL < \mu < USL$. The two definitions of C_{pk} are presented interchangeably and are equivalent when $0 \leq k \leq 1$.

The generalized analogs of these measures do not assume T to be the midpoint of the specifications and are

$$C_{pu}^* = \frac{USL - T}{3\sigma} \left(1 - \frac{|T - \mu|}{USL - T} \right) \quad (7)$$

$$C_{pl}^* = \frac{T - LSL}{3\sigma} \left(1 - \frac{|T - \mu|}{T - LSL} \right) \quad (8)$$

$$C_{pk}^* = \min(C_{pl}^*, C_{pu}^*) \quad (9)$$

and

$$C_{pm}^* = \frac{\min[USL - T, T - LSL]}{3\sqrt{\sigma^2 + (\mu - T)^2}} \quad (10)$$

A hybrid of these measures, C_{pmk} , is defined to be

$$C_{pmk} = \frac{\min[USL - \mu, \mu - LSL]}{3\sqrt{\sigma^2 + (\mu - T)^2}} \quad (11)$$

Individually C_{pu} , C_{pu}^* , C_{pl} , and C_{pl}^* consider only unilateral tolerances (i.e., USL or LSL respectively) in assessing process capability. Each uses 3σ as a measure of actual process spread, while the distance from where the process is centered (μ) to the USL (for C_{pu}) or LSL (for C_{pl}) is used as a measure of

2 Process Capability Indices, Comparison of

allowable process spread. Both C_{pu} and C_{pl} compare the length of one tail of the **normal distribution** (3σ) with the distance between the process mean and the respective specification limit. In the case of bilateral tolerances, C_{pu} and C_{pl} have an inverse relationship and individually do not provide a complete assessment of process capability. However, conservatively taking the minimum of C_{pu} and C_{pl} results in the bilateral tolerance measure defined as C_{pk} . Similarly C_{pu}^* and C_{pl}^* use adjusted distances between their respective specification limits and μ that incorporate the target in assessing allowable spread.

C_{pm} incorporates a measure of proximity to the target by replacing the process variance in the definition of C_p , with the process mean square error around the target. C_p and C_{pm} are identical when the process is centered at the target (i.e., $\mu = T$). But since C_p is not a valid measure of process capability when the process is not centered at the target, C_{pm} dominates C_p as a measure of process capability.

C_{pl}^* , C_{pu}^* , C_{pk}^* , C_{pm}^* , and C_{pmk} form the basis for a large number of process capability indices, sometimes referred to as third generation. Effectively these indices extend the class of allowable/customer process requirements versus actual process spread/performance by allowing the target to be other than the midpoint of the specification limits.

By definition, each of C_p , C_{pl} , C_{pu} , C_{pk} , C_{pm} , their generalized analogues, and C_{pmk} are unitless, thereby fostering comparisons among and within processes, regardless of the underlying mechanics of the product or service being monitored. In all cases, as process performance improves, either through reductions in variation and/or moving closer to the target, these indices increase in magnitude. As process performance improves relative to customer requirements, customer satisfaction increases as the process has a greater ability to be near the target. In all cases larger index values indicate a more capable process. Using the indices to assess the ability of the process to meet customer expectations, with larger values of the indices indicating a higher customer satisfaction and lower values, a poorer customer satisfaction is consistent with the concept of “fitness for use”.

A unified index, C_{pw} [3] of the form

$$C_{pw} = \frac{USL - LSL}{6\sqrt{\sigma^2 + w(\mu - T)^2}} \quad (12)$$

can, by varying w , be used to represent a wide spectrum of capability indices.

Allowing w to take on various values permits C_{pw} to assume equivalent computational algorithms for a variety of indices, including C_p , C_{pm} , C_{pk} , and C_{pmk} . For example, setting $w = 0$, results in

$$C_{pw} = \frac{USL - LSL}{6\sqrt{\sigma^2}} = C_p \quad (13)$$

while for $w = 1$,

$$C_{pw} = \frac{USL - LSL}{6\sqrt{\sigma^2 + (\mu - T)^2}} = C_{pm} \quad (14)$$

Defining $d = \frac{USL - LSL}{2}$, $a = \mu - \frac{USL + LSL}{2}$ and $p = \frac{|\mu - T|}{\sigma}$ then

$$w = \begin{cases} \left(\frac{d^2}{(d - |a|)^2} - 1 \right) \frac{1}{p^2} & 0 < p \\ 0 & \text{elsewhere} \end{cases} \quad (15)$$

allows $C_{pw} = C_{pk}$.

Similarly,

$$w = \begin{cases} \frac{k(2 - k)}{(1 - k)^2 p^2} & 0 < k < 1 \\ 0 & \text{elsewhere} \end{cases} \quad (16)$$

where $k = \frac{2|T - \mu|}{USL - LSL}$, allows $C_{pw} = C_{pk}^*$, while

$$w = \begin{cases} \left(\frac{d}{d - |a|} \right)^2 \left(\frac{1}{p^2} + 1 \right) - \frac{1}{p^2}, & 0 < p \\ 0 & \text{elsewhere} \end{cases} \quad (17)$$

elsewhere results in $C_{pw} = C_{pmk}$. Table 1 includes several weights including the appropriate weights associated with $C_p(u, v)$ [4].

It is important to note that the universal assumptions associated with the unified index C_{pw} include that the underlying process is stable and the process measurements are normally distributed.

Interpreting Process Capability Measures

Process capability measures have traditionally been used to provide insights into the number (or proportion) of a nonconforming product (i.e., yield). Practitioners cite a C_p value of 1 as representing 2700 ppm

Table 1 Other C_{pw} weights and the associated index

w	Resulting index
$\begin{cases} \frac{6C_p - p}{(3C_p - p)^2 p}, & 0 < \frac{p}{3} < C_p \\ 0, & \text{elsewhere} \end{cases}$	$C_{pk}^* = (1 - k) \frac{USL - LSL}{6\sigma}$
$\begin{cases} \left(\frac{d}{d - a } \right)^2 \left(\frac{1}{p^2} + 1 \right) - \frac{1}{p^2}, & 0 < p \\ 0, & \text{elsewhere} \end{cases}$	$C_{pmk} = \frac{\min(USL - \mu, \mu - LSL)}{3\sqrt{\sigma^2 + (\mu - T)^2}}$ $= \frac{d - \mu - M }{3\sqrt{\sigma^2 + (\mu - T)^2}}$
$\begin{cases} \left(\frac{d}{d - u a } \right)^2 \left(\frac{1}{p^2} + v \right) - \frac{1}{p^2}, & 0 < p \\ 0, & \text{elsewhere} \end{cases}$	$C_p(u, v) = \frac{d - u \mu - M }{3\sqrt{\sigma^2 + v(\mu - T)^2}}$

nonconforming, while 1.33 represents 63 ppm; 1.66 corresponds to 0.6 ppm; and 2 indicates <0.1 ppm. C_{pk} has similar connotations with a C_{pk} of 1.33 representing a maximum of 63 ppm nonconforming. Practitioners use the value of the process capability index and its associated number, nonconforming, to identify capable processes. A process with a C_p greater than or equal to 1 has traditionally been deemed capable, while a C_p of less than 1 indicates that the process is producing more than 2700 ppm nonconforming and used as an indication that the process is not capable of meeting customer requirements. In the case of C_{pk} , the auto industry frequently uses 1.33 as a benchmark in assessing the capability of a process.

Inherent in any discussion of yield as a measure of process capability is the assumption that product produced just inside the specification limit is of equal quality to that produced at the target. This is equivalent to assuming a square-well loss function [5] for the quality variable (see Figure 2).

In practice the magnitudes of C_p , C_{pl} , C_{pu} , C_{pk} , their generalized analogues, and C_{pmk} are interpreted as a measure of nonconforming and therefore are represented by the square-well loss function. Any change in the magnitude of these indices (holding the customer requirements constant) is due to

changes in the distance between the specification limits and the process mean. As Boyles [6] emphatically points out “ C_{pk} does not in itself say anything about the distance between μ and T ” and “is essentially a measure of **process yield** only.” By design C_p , C_{pl} , C_{pu} , C_{pk} , C_{pl}^* , C_{pu}^* , C_{pk}^* , and C_{pmk} are used to identify changes in the amount of product beyond the specification limits (not proximity to the target) and therefore consistent with the square-well loss function.

Taguchi used the quadratic loss function to motivate the idea that a product imparts no loss, only if that product is produced at its target. He maintains that even small deviations from the target result in a loss of quality and that as the product increasingly deviates from its target, there are larger and larger losses in quality. This approach to quality and quality assessment is different from the traditional approach, where no loss in quality is assumed until the product deviates beyond its USL and LSL (i.e., square-well loss function). Taguchi’s philosophy highlights the need to have small variability around the target. Clearly in this context, the most capable process will be one that produces its entire product at the target, with the next best being the process with the smallest variability around the target.

The motivation for C_{pm} and C_{pm}^* does not arise from examining yield, but from looking at the ability of the process to be in the neighborhood of the target. This motivation has little to do with the number of nonconforming although upper bounds on the number of nonconforming can be determined for numerical values of C_{pm} [7]. Several authors [3, 6, 8] have discussed the relationship between C_{pm} and the quadratic loss function and its affinity with

Figure 2 Square-well and modified quadratic loss functions

4 Process Capability Indices, Comparison of

the philosophies that support a loss in quality for any departure from the target. The loss associated with the quality variable under investigation is then depicted using a modified quadratic loss function (see Figure 2).

C_{pk} , C_{pm} , and C_{pmk} have different functional forms, are represented by different loss functions, and have different relationships with C_p as the process drifts from the target. C_{pk} and C_{pm} are often called second-generation measures of process capability whose motivations arise directly from the inability of C_p to consider the target value. The differences in their associated loss functions demarcate the measures, while the magnitudinal relationship between C_p and C_{pk} , C_{pm} , C_{pmk} are also different. C_{pk} , C_{pm} , and C_{pmk} are functions of C_p that attempt to penalize the process for not being centered on the target (T). Expressing C_{pm} , C_{pk} , and C_{pmk} in the following manner

$$C_{pm} = \frac{1}{\sqrt{1 + \left(\frac{\mu - T}{\sigma}\right)^2}} C_p \quad (18)$$

$$C_{pk} = \left(1 - \frac{2|\mu - T|}{USL - LSL}\right) C_p \quad (19)$$

and

$$C_{pmk} = \left(1 - \frac{2|\mu - T|}{USL - LSL}\right) \left(\frac{1}{\sqrt{1 + p^2}}\right) C_p \quad (20)$$

illustrates the “penalizing” relationship between C_p and C_{pm} , C_{pk} , C_{pmk} respectively. As the process mean drifts from the target (measured by $p = \frac{|\mu - T|}{\sigma}$), C_{pm} , C_{pk} , and C_{pmk} decline as a percentage of C_p (see Figure 3). In the case of C_{pm} , this relationship is independent of the magnitude of C_p . On the other hand, the decline in C_{pk} and C_{pmk} as a percentage of C_p depends on the magnitude of C_p . For example, in Figure 3, $C_{pk}(1)$, $C_{pk}(2)$, and $C_{pk}(3)$ represent the relationships between C_{pk} and C_p for $C_p = 1$, $C_p = 2$ and $C_p = 3$, respectively. Similarly $C_{pmk}(1)$, $C_{pmk}(2)$, and $C_{pmk}(3)$ represent the relationships between C_{pmk} and C_p for $C_p = 1$, $C_p = 2$, and $C_p = 3$.

C_{pk} , C_{pmk} , and C_{pm} have different functional forms, are represented by different loss functions, and have different relationships with C_p as the process drifts from the target. Hence, although C_{pm} and C_{pk} are lumped together as second-generation measures and C_{pmk} as a hybrid of the two, all are different in their development and assessment of process capability. A discussion on the relationship of capability indices (C_p , C_{pk} , and C_{pm}) among themselves, linked to specifications at the supplier level and specifications to the assembly

Figure 3 Comparison of C_p , C_{pk} , C_{pm} , and C_{pmk}

level is cited in [9]. Similarly C_{pk}^* and C_{pmk}^* differ from C_{pm}^* in their assessment of process capability.

Effects of Nonnormality

If the process measurements do not arise from a normal distribution, none of the indices discussed provides valid measures of yield. Each index uses a function of σ as a measure of actual process spread in its determination of process capability. But as many authors [10–13] have pointed out, although the standard deviation has become synonymous with the term dispersion, its physical meaning need not be the same for different families of distributions, or for that matter, within a family of distributions. Therefore the actual process spread (a function of 6σ) does not provide a consistent meaning over various distributions. To illustrate, suppose that precisely 99.73% of the process measurements fall within the specification limits (i.e., a yield of 2700 ppm). The values of C_p , C_{pl} , C_{pu} , C_{pk} , C_{pm} , and C_{pmk} are 0.5766, 0.7954, 1.0000, 1.2210, and 1.4030 respectively when the measurements arise from a uniform, triangular, normal, logistic, and double exponential distribution. As long as 6σ carries a yield interpretation when assessing process capability (i.e., is translated into ppm nonconforming), none of the indices should be used if the underlying process distribution is not normal.

If we assume process capability assessments to be studies of the ability of the process to produce product around the target, then C_{pm}^* and C_{pmk}^* provide practitioners with an assessment of capability regardless of the distribution associated with the measurements. Clustering around the target, rather than a measure of nonconforming releases the physical meaning attached to 6σ . The denominators of C_{pm}^* and C_{pmk}^* then provide a measure of the clustering around the target and compare this with customer tolerance.

Eliminating the physical meaning of ppm and investigating Euclidean distances around the target allows C_{pm} and C_{pmk} to compare the capability of various processes, or processes over time, regardless of the underlying distribution. The underlying distribution will impact the inferences that can be made from samples gathered from the population; however, the population parameter is no longer distributionally sensitive.

Process Capability Plots

Introduction

When measuring the capability of a manufacturing process, some form of process capability index is often used (*see Process Capability Indices, Comparison of*). Vännman [1] unified the most common indices by a family of capability indices, defined as

$$C_p(u, v) = \frac{d - u|\mu - T|}{3\sqrt{\sigma^2 + v(\mu - T)^2}} \quad (1)$$

where $u \geq 0, v \geq 0, \mu$ is the process mean and σ is the process standard deviation of the in-control process. In equation (1) the target value T equals the midpoint of the specification interval $[LSL, USL]$. Furthermore, $d = (USL - LSL)/2$, i.e. half the length of the specification interval. Setting $u = 0$ or 1 and $v = 0$ or 1 in equation (1) we obtain $C_p(0, 0) = C_p$, $C_p(1, 0) = C_{pk}$, $C_p(0, 1) = C_{pm}$, and $C_p(1, 1) = C_{pmk}$. When using process capability indices, a process is defined to be capable if the process capability index exceeds a certain threshold value $k > 0$. Some commonly used values are $k = 1, 4/3, 5/3$.

Assume that we use an index defined by the family $C_p(u, v)$ in equation (1) and define the process to be capable if $C_p(u, v) > k$, for given values of u, v , and k . Different choices of u, v , and k impose different restrictions on the process parameters (μ, σ) . This is easily seen in a process capability plot, which is a contour plot of $C_p(u, v) = k$ as a function of μ and σ , or as a function of μ_t and σ_t , where

$$\mu_t = \frac{\mu - T}{d} \quad \text{and} \quad \sigma_t = \frac{\sigma}{d} \quad (2)$$

The contour curve is obtained by rewriting the index in equation (1) as a function of μ_t and σ_t , solving the equation $C_p(u, v) = k$ with respect to σ_t and then plotting σ_t as a function of μ_t . We easily find that $C_p(u, v) = k$ is equivalent to

$$\sigma_t = \sqrt{\frac{(1 - u|\mu_t|)^2}{9k^2} - v\mu_t^2},$$

$$|\mu_t| \leq \frac{1}{u + 3k\sqrt{v}}, \quad (u, v) \neq (0, 0) \quad (3)$$

When $u = v = 0$, i.e. when considering the index $C_p = k$, we have

$$\sigma_t = \frac{1}{3k}, \quad |\mu_t| \leq 1 \quad (4)$$

The reason for making the contour plot a function of (μ_t, σ_t) instead of a function of (μ, σ) is to obtain a plot where the scale is invariable, irrespective of the values of the specification limits. This is useful when considering several different characteristics (see the section titled “Several Characteristics in the Same Plot”).

To obtain the expression for σ_t in the case of C_{pk} , we let $u = 1$ and $v = 0$ in equation (3) and find that the contour curve is composed of two straight lines. To obtain the expression for σ_t in the case of C_{pm} , we let $u = 0$ and $v = 1$ in equation (3) and find that the contour curve is a semicircle (see Figure 1).

Values of the process parameters μ and σ which give (μ_t, σ_t) values inside the region bounded by the contour curve $C_p(u, v) = k$ and the μ_t axis will give rise to a $C_p(u, v)$ value larger than k , i.e. a capable process. We call this region the capability region. Furthermore, values of μ and σ which give (μ_t, σ_t) values outside this region will give a $C_p(u, v)$ value smaller than k , i.e. a non-capable process.

Note that the process capability plot is based on the process parameters, which are usually unknown in practice. Hence, this plot is a theoretical process capability plot useful to understand the restrictions the index puts on the process parameters. But it cannot immediately be used to deem if a process is capable, since it does not take the randomness of the estimators of the process parameter into account. The following sections discuss how to deal with the case in which the process parameters μ and σ are unknown.

Estimated Process Capability Plots

The process capability plot can now be generalized to an estimated process capability plot, which can be used to judge if a process is capable, when the process parameters μ and σ are unknown and need to be estimated. We assume that the studied characteristic of the process is normally distributed. Let $X_1, X_2, \dots, X_n$ be a random sample from a normal distribution with mean μ and variance σ^2 as the parametric process quality indicators.

2 Process Capability Plots

Figure 1 (a) The process capability plot for $C_{pm} = 1$. (b) The contour curves for the process capability indices C_p , C_{pk} , C_{pm} , and C_{pmk} when $k = 1$. The region bounded by the contour curve and the μ_t axis is the corresponding capability region

To obtain an appropriate decision rule we consider a hypothesis test with the null hypothesis $H_0: C_p(u, v) \leq k_0$ and the alternative hypothesis $H_1: C_p(u, v) > k_0$. As a test statistic we use the estimator $\hat{C}_p(u, v)$, which is obtained by estimating μ and σ^2 with their maximum-likelihood estimators, i.e.

$$\hat{\mu} = \bar{X} = \frac{1}{n} \sum_{i=1}^n X_i \quad \text{and} \quad \hat{\sigma}^2 = \frac{1}{n} \sum_{i=1}^n (X_i - \bar{X})^2 \quad (5)$$

The null hypothesis is rejected, and the process is deemed capable, whenever $\hat{C}_p(u, v) > c_\alpha$, where the constant $c_\alpha > k_0$ is determined so that the **significance level** of the test is α . Details of how to obtain the critical value c_α can be found, e.g. in Vännman [2, 3]. Hubele and Vännman [4] showed that, when using the capability index C_{pm} , the critical value at significance level α is obtained as

$$c_\alpha = k_0 \sqrt{n / \chi_{\alpha, n}^2} \quad (6)$$

where $\chi_{\alpha, n}^2$ is the α th quantile from a χ^2 distribution with n **degrees of freedom**. When using the capability index C_{pk} it can be shown that the critical value at significance level α is obtained from the equation

$$\int_{-\infty}^{3k_0\sqrt{n}} F_\xi \left(\frac{(3k_0\sqrt{n} - z)^2}{9c_\alpha^2} \right) f_\eta(z) dz = \alpha \quad (7)$$

where F_ξ denotes the cumulative distribution function of a central χ^2 distribution with $n - 1$ degrees of

freedom and f_η denotes the probability density function of the standardized normal distribution $N(0, 1)$. For arbitrary values of $u \geq 0$ or $v \geq 0$ the critical value c_α is determined so that the probability $P(\hat{C}_p(u, v) > c_\alpha)$ is at most α for all values of (μ_t, σ_t) such that $C_p(u, v) = k_0$, where

$$\begin{aligned} P(\hat{C}_p(u, v) > c_\alpha) &= \int_{\frac{-\sqrt{n}/\sigma_t}{u+3c_\alpha\sqrt{v}}}^{\frac{\sqrt{n}/\sigma_t}{u+3c_\alpha\sqrt{v}}} F_\xi \left(\frac{(\sqrt{n}/\sigma_t - u|t|)^2}{9c_\alpha^2} - vt^2 \right) \\ &\quad \times f_\eta \left(t - \frac{\mu_t\sqrt{n}}{\sigma_t} \right) dt \end{aligned} \quad (8)$$

MATLAB codes for solving equation (7), as well as for determining the critical value c_α for arbitrary values of u and v using equation (8), can be obtained from the author.

The estimated process capability plot is then obtained by replacing μ , σ , and k in equations (2–4) with $\hat{\mu}$, $\hat{\sigma}$, and c_α , respectively, and plotting the contour curve $\hat{C}_p(u, v) = c_\alpha$ as a function of $\hat{\mu}_t$ and $\hat{\sigma}_t$. We can now use the estimated process capability plot to define an estimated capability region as the region bounded by the contour curve $\hat{C}_p(u, v) = c_\alpha$ and the $\hat{\mu}_t$ axis. To determine if a process can be deemed capable we first calculate

$$\hat{\mu}_t = \frac{\hat{\mu} - T}{d} \quad \text{and} \quad \hat{\sigma}_t = \frac{\hat{\sigma}}{d} \quad (9)$$

Figure 2 The estimated process capability plot defined by $\hat{C}_{pm} = c_{0.05} = 1.151$. In (a) the first sample with the observed value of $(\hat{\mu}_t, \hat{\sigma}_t)$ outside the estimated capability region, illustrates a non-capable process. In (b) the second sample, with observed value of $(\hat{\mu}_t, \hat{\sigma}_t)$ inside the estimated process capability region, illustrates a capable process

Then the point $(\hat{\mu}_t, \hat{\sigma}_t)$ is plotted in the estimated process capability plot. If this point is inside the estimated capability region, the process will be considered capable at significance level α .

To illustrate the estimated process capability plot we use an example from Vännman [2], where the process is defined capable if $C_{pm} > 1$ and the significance level is $\alpha = 5\%$. The example consists of two datasets, each of size 80, from a process where $T = 8.70$ and $d = 0.24$. When $n = 80$ and $k_0 = 1$ we get the critical value $c_{0.05} = 1.151$ from equation (6). First a random sample was taken from a process, giving rise to estimates of μ and σ being equal to $\hat{\mu} = 8.6234$ and $\hat{\sigma} = 0.0519$, respectively. Later, a second random sample was taken from the same process, after it had been adjusted. Then, from the second sample, the obtained estimates of μ and σ were equal to $\hat{\mu} = 8.6628$ and $\hat{\sigma} = 0.0516$, respectively.

On the basis of the sample data, we find the estimated values of μ_t and σ_t to be $\hat{\mu}_t = (\hat{\mu} - T)/d = -0.319$ and $\hat{\sigma}_t = \hat{\sigma}/d = 0.216$ for the first sample, and $\hat{\mu}_t = -0.155$ and $\hat{\sigma}_t = 0.215$ for the second sample. We then plot the contour curve $\hat{C}_p(u, v) = c_\alpha = 1.151$ together with the points with coordinates $(-0.319, 0.216)$ and $(-0.155, 0.215)$, for the first and second sample, respectively (see Figure 2).

We can see that for the first sample, the point $(-0.319, 0.216)$ is outside the estimated capability region and hence the process cannot be considered capable. For the second sample, the point $(-0.155, 0.215)$ is now inside the estimated capability region and hence the process can be deemed capable at the 5% significance level.

What is obvious from the graphical method used here is that the non-capability in Figure 2(a) is, to a

large extent, due to the deviation of the process mean from the target value. By looking at the estimated process capability plot we get information instantly about both the deviation from the target value and the process spread as well as information about the capability. We can also see how much the deviation from target must be reduced in order to achieve a capable process.

Safety Regions

As an alternative to the estimated process capability plot, we can use the theoretical process capability plot together with a safety region. A safety region is a region plotted in the theoretical process capability plot for drawing conclusions about process capability at a given significance level. It is built around the estimated point $(\hat{\mu}_t, \hat{\sigma}_t)$ to take the randomness of the estimator $(\hat{\mu}_t, \hat{\sigma}_t)$ into account. The size of the region is determined in such a way that it corresponds to significance level α .

Vännman [3] suggests putting a circular safety region around the estimated point $(\hat{\mu}_t, \hat{\sigma}_t)$. The circular safety region is defined as the region bounded by the circle

$$(\delta - \hat{\mu}_t)^2 + (\gamma - \hat{\sigma}_t)^2 = R^2 \hat{\sigma}_t^2 \quad (10)$$

The constant R depends on the sample size n and the significance level α . The process is deemed capable if the whole circular safety region in equation (11) is inside the capability region in the theoretical process capability plot defined by $C_p(u, v) = k_0$. The constant R is chosen so that the

4 Process Capability Plots

Figure 3 The process capability plot defined by $C_{pm} = 1$ together with the circular region. In (a) the process cannot be considered capable, but in (b) the whole circle is inside the capability region and hence the process is considered capable at 5% significance level

probability that the circular safety region is inside the capability region, given that $C_p(u, v) = k_0$, is at most equal to α . When using the index C_{pm} to define a capable process, the probability $\Pi(\mu_t, k_0)$ that the circular region is inside the capability region defined by $C_{pm} = k_0$, given that $C_{pm} = k_0$, can be expressed as follows.

$$\Pi(\mu_t, k_0) = \int_0^{Q(\mu_t, k_0)} F_\tau((S(\mu_t, k_0) - R\sqrt{y})^2 - y) f_\xi(y) dy \quad (11)$$

where

$$S(\mu_t, k_0) = \sqrt{\frac{n}{1 - 9k_0^2\mu_t^2}} \quad \text{and} \quad Q(\mu_t, k_0) = \frac{S(\mu_t, k_0)^2}{(R + 1)^2} \quad (12)$$

F_τ denotes the cumulative distribution function of a noncentral χ^2 distribution with 1 degree of freedom and noncentrality parameter λ , where λ is

$$\lambda = \frac{(\mu - T)^2 n}{\sigma^2} = \frac{\mu_t^2 n}{\sigma_t^2} \quad (13)$$

f_ξ denotes the probability density function of a central χ^2 distribution with $n - 1$ degrees of freedom. The probability in equation (11) is defined for $|\mu_t| < 1/(3k)$. The constant R is determined so that the probability $\Pi(\mu_t, k_0)$ in equation (11) is at most α for all values of μ_t such that $C_{pm} = k_0$. MATLAB codes for determining the R -value using equation (11) can be obtained from the author.

If we apply this circular safety region to the previous example, where $n = 80$ and $\alpha = 0.05$ and the process is defined as capable when $C_{pm} > 1$, we find $R = 0.1903$. In Figure 3 we see the circular regions plotted. The conclusions about the process capability are the same as before.

Deleryd and Vännman [5] suggest a rectangular safety region. This region is, however, less powerful than the circular safety region.

Several Characteristics in the Same Plot

Several characteristics of a process can be monitored in the same plot and at the same time the information on the location and spread of the process is retained. As an example consider the following situation. Three different quality characteristics A , B , and C are of interest. They have the following different

Figure 4 The estimated process capability plot defined by $\hat{C}_{pm} = c_{0.01} = 1.199$. A , B , and C indicate the observed value of $(\hat{\mu}_t, \hat{\sigma}_t)$ for the three characteristics A , B , and C , respectively

Figure 5 Process capability plots with circular regions for each of characteristics A , B , and C , each at 1% significance level. In (a) the sample sizes differ. In (b) all have sample size 50. The observed values of $(\hat{\mu}_t, \hat{\sigma}_t)$ are the same in (a) and (b)

specification intervals: A : [200, 210]; B : [12.0, 16.0]; C : [1.40, 2.20], with target values equal to the midpoints of each interval. They are assumed to be normally distributed and in statistical control. The process will be considered capable when all three characteristics are considered capable according to the definition that $C_{pm} > 1$.

A sample of size 50 is taken from each of the three characteristics and the point $(\hat{\mu}_t, \hat{\sigma}_t)$ is calculated for each of them. The decision rule is that the process will be considered capable if all three points $(\hat{\mu}_t, \hat{\sigma}_t)$ fall inside the estimated capability region, where the significance level for the estimated capability curve is 1%. Then, according to Bonferroni's inequality, the significance level for the decision rule will be at most 3%. The critical value, when $n = 50$ and $\alpha = 0.01$, is $c_{0.01} = 1.199$ according to equation (6). In Figure 4 we can see the results having the following observed values of $(\hat{\mu}_t, \hat{\sigma}_t)$: A : (0.05, 0.20); B : (0.25, 0.24); C : (-0.15, 0.17).

In Figure 4 we cannot consider the process to be capable, since characteristic B falls outside the semicircle. Figure 4 shows that from one single plot we get, for each of the three characteristics A , B , and C , information about the deviation from target and the standard deviation, as well as information on how to adjust the process to make it capable, if it is not capable.

When monitoring several characteristics in the estimated process capability plot, the same sample size is needed for each characteristic. With different sample sizes, the safety regions can be used instead. Figure 5 shows an example of this situation. In Figure 5(a) the sample size for characteristic A is 50, for B is 30, and for C is 70. Figure 5(b) illustrates the same example as in Figure 4.

Conclusions

The graphical methods discussed here are efficient in the respect that in one single plot we get visual information simultaneously about the location and spread of the studied characteristic, as well as information about the capability of the process at a given significance level. We can at a glance relate the deviation from target and the spread to each other and to the capability index in such a way that we are able to see whether the non-capability is caused by the fact that the process output is off target, or that the process spread is too large, or if the result is a combination of these two factors. Furthermore, we can easily see how large a change is needed to obtain a capable process. For more details regarding the different plots, see Vännman [2, 3] and Deleryd and Vännman [5].

KERSTIN VÄNNMAN

Yield Surface Modeling

Introduction

Yield surface modeling™ (YSM) is a multiple-response optimization method developed and patented by Maass and Feldbaumer [1]. YSM is particularly well-suited for use with simulation. If the dependence of a set of critical parameters on a shared set of manufacturing and design factors (some of which experience part-to-part manufacturing variability) can be simulated, YSM can determine settings where the critical parameters are robust against manufacturing variability. The output can be a **response surface** or contour plot, but one in which the response plotted as a function of the factors is either the composite yield or the composite C_{pk} (*see Multi-variate Process Capability Indices, Comparison of; Process Capability Indices, Comparison of; Control Charts and Process Capability*) for multiple responses compared with the specification limits.

YSM™ expands on response surface modeling (RSM), which can explore effects of factors on each of several critical parameters or responses. YSM uses the set of equations provided by RSM to predict the composite yield for the set of critical parameters and enables determination of settings of the factors that will provide acceptable composite yield and composite C_{pk} .

The rationale for using composite yield and composite process capability, C_{pk} , follows this reasoning: each individual critical parameter to be optimized can be in different units (such as volts, seconds, kilograms, or millimeters) and has different specification limits in those units. The degree of “goodness” of projected performance for each critical parameter cannot be directly combined – rather, each critical parameter needs to be converted to an index that is unit-less prior to combination. C_{pk} is unit-less and compares the expected value of the critical parameter to its nearest specification limit, then divides the difference by three times the projected standard deviation for the critical parameter. C_{pk} is a “higher is better” index, and a C_{pk} value of 1.5 is considered consistent with **Six Sigma** capability. Assuming normality, and assuming that the part of the distribution that would fall beyond the nearest specification limit would be rejected, the C_{pk} value is directly related to projected yield for that requirement. Projected yield

for each requirement is another index that is unit-less. The process capabilities for several critical parameters can be combined into a composite C_{pk} , assuming independence. Similarly, projected yields for several critical parameters can be combined into a composite yield index, assuming independence. These resulting composite indices not only allow multiple responses in different units to be combined, but can be predictive indices for the average yield of the product if the product’s performance is tested for this set of critical parameters, with each critical parameter being tested relative to its associated specification limits.

Success Stories

YSM has been used in the development of 60 integrated circuits (ICs) and in a clinical sensor; all products were first-pass successes with higher yield than comparable products. Figure 1 illustrates the results for a family of logic devices (ICs). Prior to using YSM, the first few devices had low yields and the logic family was up for cancellation. After optimization using YSM with Simulation Program with Integrated Circuit Emphasis (SPICE) simulation, the yield for subsequent devices increased from 56% initially to 90–100%, resulting in 57 first-pass successful new products introduced in 28 weeks. This set a record for the company and led to hundreds of millions in sales and over 100 million in profits.

YSM was used to identify and assist in the resolution of yield sensitivity in the design of a new clock driver prior to tapeout (Figure 2). This resulted in a successful clock driver IC family, and over 50 million in sales and 25 million in profits.

Assumptions and Formulas

YSM™ uses these assumptions:

- The polynomial equations obtained through RSM estimate the mean or expected value for each response, $E(Y_i)$, for the combinations of set of factor levels corresponding to that point on the response surface (equation 1).
- The variance for each response at the same combinations of factor levels can be estimated using the Generation of System **Moments** method based on a Taylor Series Expansion, as given in equation (2) [2].

Figure 1 Improvement in yield surface from the original design (a) through a process change (b) and a change in the buffer design (c) that combined to provide a smooth yield surface corresponding to a robust, high yield design (d)

- The factors are uncorrelated. Exceptions to this assumption can be handled with an additional term in the Taylor Series Expansion [3].
- Each response is normally distributed.
- The composite yield for multiple responses can be estimated as the product of the expected percent lying within the specification limits for each response, as given in equations (4) and (6).

The sequence for developing a yield surface use equations (1–6), as shown in Figure 3.

$$E(Y_j) = f(x_1, x_2, \dots, x_n) \quad (1)$$

$$\text{Var}(Y_j) = \sum_{i=1}^N \left(\frac{\partial Y_j}{\partial X_i} \right)^2 \text{Var}(X_i) \quad (2)$$

$$C_{pk}(Y_j) = \min \left\{ \left(\frac{USL - E(Y_j)}{3 \times S(Y_j)} \right), \left(\frac{E(Y_j) - LSL}{3 \times S(Y_j)} \right) \right\} \quad (3)$$

$$\text{Yield}(Y_j) = \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{3 \times C_{pk}} (Y_j) \exp \left(-\frac{u^2}{2} \right) du \quad (4)$$

$$\text{Composite } C_{pk} = \min(C_{pk}(Y_1), C_{pk}(Y_2), \dots,$$

$$C_{pk}(Y_p)) \quad (5)$$

$$\text{Composite yield} = \prod_{j=1}^P \text{Yield}(Y_j) \quad (6)$$

Figure 2 Yield surface model for a clock driver prior to tapeout for first-pass prototyping. The yield surface showed that the first design was highly sensitive to the channel length and would have low yield with the current process

Figure 3 Method to develop a composite yield surface from RSM for multiple responses

Case Study: Integrated Alternator Regulator (IAR) IC for Automotive

The IAR was a bipolar IC designed by Stephen Dow of Motorola for use in the ignition system for automobiles. YSM™ was performed in conjunction with SPICE, a circuit simulator. A central composite design (CCD) (*see Central Composite Designs*) was set up to vary the levels of four factors that were monitored in the manufacturing area: current gain of bipolar transistors, capacitance of an on-chip capacitor built using a silicon-nitride dielectric, and resistances for two types of resistors.

The results for four critical parameters required for acceptable performance were obtained through SPICE simulation at each combination of levels for these factors. Figure 4 shows the response surfaces for the mean and variance for one critical parameter, soft start time, and the mean and variance combined to develop a response surface for the predicted Z or C_{pk} (referred to as a C_{pk} Surface) followed by the conversion of the C_{pk} surface into a yield surface. This resulting yield surface represents the expected percentage of good parts obtained with that combination of factor levels, subject to the given set of assumptions. Figure 5 illustrates the combination of composite C_{pk} and yield surfaces for the four responses.

Figure 4 Response surface for the expected value (a) and the variance (b) for the critical parameter soft start time is translated into a response surface for C_{pk} (c) and yield (d)

Figure 5 C_{pk} s and yields for all four critical parameters are combined into surfaces for composite C_{pk} (a) and composite yield (b)

YSM Strengths and Comparison with Alternatives

YSM can be used to optimize multiple responses, and predicts the composite yield and composite C_{pk} for those multiple responses. Alternative approaches include overlaid contour plots, **Monte Carlo simulation**, and the use of desirability functions.

An overlay of contour plots can be used to find a **feasible region** where all responses can fall within the specification limits – this only assures that the C_{pk} will be greater than zero and the yield for each response will be greater than 50%. With multiple responses, the composite yield can be substantially below 50% within the feasible region. By contrast, YSM can be used to find a region with very high yield, as illustrated in Figures 1, 2, 4 and 5.

Monte Carlo simulation predicts yield for one response at a time, if the input variables were centered as selected. Stochastic optimization combined with Monte Carlo simulation (as with Crystal Ball™ with OptQuest™) can be used to find settings that optimize the predicted C_{pk} of one response while restricting

the predicted C_{pk} 's for other responses to be more than some minimal value. This approach can provide a stochastic optimum, but YSM provides a means to visualize the sensitivity in the region that Monte Carlo simulation can miss – the latter does not show when the optimum settings are close to a “cliff” where a slight shift can result in disastrously lower yields.

Both Monte Carlo simulation and YSM can provide useful sensitivity analysis. With YSM, the sensitivity analysis comes directly from equation (2), where the magnitude of each contributor to the total variance of each response is proportional to the square of the product of the partial derivative of the response to each x_i times the variance of x_i . This is illustrated with Figure 6, which comes from the automotive IAR case study described earlier. This sensitivity analysis helps to provide guidance as to which factors should be focused on in order to reduce the variance of responses with low predicted C_{pk} and yield.

YSM can also handle correlated input variables by adding more terms from the Taylor Series Expansion (expanded versions of equations 1 and 2).

Figure 6 Percent of variance of the response, soft start time, to the variation of each factor for the automotive IAR case study

Summary

YSM has been used in the successful development of several new products. Although most of

the successful uses have been in IC development, this approach has also been used on other products including the optimization of the mechanical design for a two-way radio and the development of a complex medical sensor for DNA sequences, indicating a larger range of potential applications. To date, every new product that has been developed using YSM has been a first-pass success with high yield. This was considered so remarkable by the former president of Motorola Semiconductor Product Sector that, at his request, the approach was treated as proprietary information for several years.

Process Yield

Process Yield

Process yield has, for a long time, been the most common and standard criterion used in various manufacturing industries to characterize the process performance. Process yield is currently defined as the percentage of the processed product units passing inspection. That is, the product characteristic, X , must fall within the preset specification interval.

For processes involving two-sided manufacturing specifications, the process yield can be calculated as: $Yield = \Pr(LSL < X < USL)$, where USL and LSL are the upper and the lower specification limits, respectively. For the-smaller-the-better processes whose preset specifications require only the upper specification limit USL , the process yield is: $Yield = \Pr(X < USL)$. For the-larger-the-better processes whose preset specifications require only the lower specification limit LSL , the process yield is: $Yield = \Pr(X > LSL)$.

Suppose the production process is operating in a stable manner such that the fraction of the nonconformities (NC), the probability that any unit will not conform to specifications, is $P(\text{NC})$, and that successive units produced are independent. Note that $P(\text{NC}) = 1 - Yield$. If a random sample of n units of a product is selected and D is the number of units of the product that are nonconforming, then D follows $b(n, p)$ with $p = P(\text{NC})$, a binomial distribution with parameters n and p . Generally, the actual fraction of nonconformities, p , is unknown. Traditionally, the parameter p is estimated by the sample fraction nonconforming, the estimated p , which is defined as: $\hat{p} = D/n$. The actual $Yield$ of a process is also unknown, which can be estimated by $1 - \hat{p} = (n - D)/n$.

The above approach is applicable only for processes with large $P(\text{NC})$, say, $p \geq 0.01$. For processes with small p it is inappropriate, since $\hat{p}$ will be most likely zero in most cases.

Process Capability Indices

Process capability indices (PCIs) are intended to provide single-number assessments of the ability to

meet specification limits on quality characteristic(s) of interest. Existing PCIs, C_p , C_a , C_{PU} , C_{PL} , C_{pk} , C_{pm} , and C_{pmk} have been proposed to the manufacturing industry as capability measures based on various criteria including process variation, departure, yield, and loss. The process yield is one of the important factors, though not the only one, considered when accessing or improving a process. In this article, PCIs dedicated to the measurement of the yield of normally distributed processes with two-sided specification limits as well as one-sided specification limit are discussed. These indices are explicitly defined as follows [1–4, **Process Capability Indices, Comparison of**]:

$$\begin{aligned} C_p &= \frac{USL - LSL}{6\sigma}, C_a = 1 - \frac{|\mu - m|}{d}, \\ C_{PU} &= \frac{USL - \mu}{3\sigma}, C_{PL} = \frac{\mu - LSL}{3\sigma}, \\ C_{pk} &= \min \left\{ \frac{USL - \mu}{3\sigma}, \frac{\mu - LSL}{3\sigma} \right\}, \\ C_{pm} &= \frac{USL - LSL}{6\sqrt{\sigma^2 + (\mu - T)^2}}, \\ C_{pmk} &= \min \left\{ \frac{USL - \mu}{3\sqrt{\sigma^2 + (\mu - T)^2}}, \right. \\ &\quad \left. \frac{\mu - LSL}{3\sqrt{\sigma^2 + (\mu - T)^2}} \right\} \end{aligned} \quad (1)$$

where μ is the process mean, σ is the process standard deviation, $m = (USL + LSL)/2$ is the midpoint of the specification interval, $d = (USL - LSL)/2$ is the half-length of the specification tolerance, and T is the target value preset by the product designer or manufacturing engineer. This paper will focus on the situation in which the target value T is set to the specification center, i.e. $T = m$, the most common case in practical applications.

The index C_p , a function of the process standard deviation σ and the specification limits, has been referred to as the *precision index* which is defined to measure the consistency of the process quality characteristic relative to the manufacturing tolerance. The index C_a , a function of the process mean and the specification limits, has been referred to as the *accuracy index*, which is defined to measure the degree of process centering relative to the manufacturing tolerance. Note that $0 \leq C_a \leq 1$ for $LSL \leq \mu \leq USL$, and

2 Process Yield

$C_a < 0$ for $\mu < LSL$ or $\mu > USL$. Especially, $C_a = 1$ for $\mu = m$.

PCIs for Two-Sided Processes

There are many capability indices including C_p , C_a , C_{pk} , C_{pm} , and C_{pmk} designed for assessing processes with two-sided specification limits (which require USL and LSL). The three indices C_{pk} , C_{pm} , and C_{pmk} may be rewritten respectively as follows

$$C_{pk} = C_p C_a, C_{pm} = \frac{C_p}{\sqrt{1 + [3C_p(1 - C_a)]^2}}, \text{ and}$$

$$C_{pmk} = \frac{C_p C_a}{\sqrt{1 + [3C_p(1 - C_a)]^2}} \quad (2)$$

which are all functions of the two basic indices C_p and C_a .

For a normally distributed process, the probability fraction of nonconforming $P(\text{NC})$ is

$$P(\text{NC}) = \Phi[-3C_p(2 - C_a)] + \Phi[-3C_p C_a] \quad (3)$$

which is also a function of the two basic indices C_p and C_a . Especially, $P(\text{NC}) = 2700$ ppm when $C_p = 1$ and $C_a = 1$, i.e. when $USL - LSL = 6\sigma$ and $\mu = m$.

Pearn and Lin [5] obtained a yield measure formula based on C_{pk} as:

$$P(\text{NC}) = \Phi[-3C_{pk}] + \Phi\left[-\frac{3C_{pk}(2 - C_a)}{C_a}\right] \quad (4)$$

for $C_{pk} > 0$ and $C_a > 0$. Based on C_{pk} , Boyles [6] noted a bound for the yield as:

$$2\Phi[3C_{pk}] - 1 \leq \text{Yield} \leq \Phi[3C_{pk}] \quad (5)$$

or

$$\Phi[-3C_{pk}] \leq P(\text{NC}) \leq 2\Phi[-3C_{pk}] \quad (6)$$

for $C_{pk} \geq 0$.

Pearn and Lin [5] also obtained a yield measure formula based on C_{pm} as

$$P(\text{NC}) = \Phi\left[-\frac{2 - C_a}{\sqrt{\frac{1}{(3C_{pm})^2} - (1 - C_a)^2}}\right]$$

$$+ \Phi\left[-\frac{C_a}{\sqrt{\frac{1}{(3C_{pm})^2} - (1 - C_a)^2}}\right] \quad (7)$$

for $(3C_{pm} - 1)/(3C_{pm}) \leq C_a \leq 1$. Based on C_{pm} , Rucinski [7] obtained a lower bound for the yield as: $\text{Yield} \geq 2\Phi(3C_{pm}) - 1$, or $P(\text{NC}) \leq 2\Phi(-3C_{pm})$ for $C_{pm} > \sqrt{3}/3$.

Furthermore, the yield measure formula based on C_{pmk} can be displayed as:

$$P(\text{NC}) = \Phi\left[-\frac{3C_{pmk}(2 - C_a)}{\sqrt{C_a^2 - [3C_{pmk}(1 - C_a)]^2}}\right]$$

$$+ \Phi\left[-\frac{3C_{pmk}C_a}{\sqrt{C_a^2 - [3C_{pmk}(1 - C_a)]^2}}\right] \quad (8)$$

for $3C_{pmk}/(1 + 3C_{pmk}) \leq C_a \leq 1$. The corresponding lower bound for the yield is: $\text{Yield} \geq 2\Phi(3C_{pmk}) - 1$, or $P(\text{NC}) \leq 2\Phi(-3C_{pmk})$ for $C_{pmk} > \sqrt{2}/3$.

Hence, $P(\text{NC}) \leq 2\Phi(-3C)$ and $0 \leq C_a \leq 1$, i.e. $LSL \leq \mu \leq USL$, for $C_{pk} = C$. $P(\text{NC}) \leq 2\Phi(-3C)$ and $(3C - 1)/(3C) \leq C_a \leq 1$, i.e. $m - d/(3C) \leq \mu \leq m + d/(3C)$, for $C_{pm} = C$. And, $P(\text{NC}) \leq 2\Phi(-3C)$ and $3C/(1 + 3C) \leq C_a \leq 1$, i.e. $m - d/(1 + 3C) \leq \mu \leq m + d/(1 + 3C)$, for $C_{pmk} = C$. The three indices C_{pk} , C_{pm} , and C_{pmk} provide the same upper bound $P(\text{NC}) \leq 2\Phi(-3C)$ when $C_{pk} = C$, $C_{pm} = C$, or $C_{pmk} = C$, but different information about the process centering measure C_a . For example, if $C_{pk} = 1.0$ we only have the information of process yield through the upper bound $P(\text{NC}) \leq 2700$ ppm. But, if $C_{pm} = 1.0$ we have the information of process yield through the upper bound $P(\text{NC}) \leq 2700$ ppm and process centering measure $0.667 \leq C_a \leq 1$. And, if $C_{pmk} = 1.0$ we have the information of process yield through the upper bound $P(\text{NC}) \leq 2700$ ppm and process centering measure $0.75 \leq C_a \leq 1$. Table 1 displays the corresponding upper bound of $P(\text{NC})$ in ppm (nonconforming parts per million - NCPPM) for various $C = 0.90(0.01)2.00$ when $C_{pk} = C$, or $C_{pm} = C$, or $C_{pmk} = C$, where $NCCPPM = 10^6 \times P(\text{NC})$. For example, for $C = 1.24$, the number of nonconformities is not greater than 200 ppm.

In general, the process mean, μ , and the process standard deviation, σ , are unknown. But, in practice μ and σ can be estimated by the

Table 1 The corresponding upper bound of $P(\text{NC})$ in ppm (NCPMP) for various $C = 0.90(0.01)2.00$ when $C_{pk} = C$, or $C_{pm} = C$, or $C_{pmk} = C$

NCPMP: nonconforming parts per million

sample mean, $\bar{X} = \sum_{i=1}^n X_i/n$, and the sample standard deviation, $S = [\sum_{i=1}^n (X_i - \bar{X})^2/(n-1)]^{1/2}$ or $S_n = [\sum_{i=1}^n (X_i - \bar{X})^2/n]^{1/2}$, to obtain the natural estimators of the three indices $\hat{C}_{pk}$, $\hat{C}_{pm}$, and $\hat{C}_{pmk}$. In order to calculate these estimators, however, sample data must be collected, and a great degree of uncertainty may be introduced into capability assessments owing to sampling errors. The approach of simply looking at the calculated values

of the estimated indices and concluding whether the given process is capable, is unreliable as the sampling errors are ignored. For normally distributed processes, the testing procedures using the natural estimators $\hat{C}_{pk}$, $\hat{C}_{pm}$, or $\hat{C}_{pmk}$ for practitioners have been developed to determine if their processes satisfy the targeted quality condition (see [8–11]).

To obtain an exact measure of the process yield, Boyles [6] considered a yield index, referred to as S_{pk} , for normally distributed processes. The index S_{pk} is defined as:

$$S_{pk} = \frac{1}{3} \Phi^{-1} \left\{ \frac{1}{2} [\Phi(3C_{PU}) + \Phi(3C_{PL})] \right\} \quad (9)$$

There is a one-to-one relationship between S_{pk} and the process yield because for a process with $S_{pk} = c$, we can obtain $Yield = 2\Phi(3c) - 1$ or $P(\text{NC}) = 2\Phi(-3c)$. Table 2 displays the number of nonconformities (in ppm) for various S_{pk} values = 0.5(0.1)2.0.

Unfortunately, the exact distribution of $\hat{S}_{pk}$, the natural estimator of the index S_{pk} , is mathematically intractable. Lee *et al.* [12] derived an approximate distribution of the estimator $\hat{S}_{pk}$ using the Taylor expansion technique. They showed that the estimator $\hat{S}_{pk}$ is approximately normally distributed. Chen and Pearn [13] used the **bootstrap** resampling technique to find the lower confidence bound on S_{pk} , so that practitioners/engineers can use them to perform quality testing and determine whether their processes meet the preset quality requirement.

PCIs for One-Sided Processes

Capability indices C_{PU} and C_{PL} have been designed specifically for assessing processes with one-sided specification limit (which require only *USL* or *LSL*). C_{PU} measures the capability of a smaller-the-better process with an upper specification limit. On the other hand, C_{PL} measures the capability of a larger-the-better process with a lower specification limit.

For a normally distributed process with one-sided specification limit *USL*, corresponding to C_{PU} value the process yield is:

$$\begin{aligned} Yield &= \Pr(X < USL) = \Phi(3C_{PU}), \text{ or} \\ P(\text{NC}) &= \Phi(-3C_{PU}) \end{aligned} \quad (10)$$

On the other hand, for a normally distributed process with one-sided specification limit LSL, corresponding to C_{PL} value the process yield is:

$$\begin{aligned} \text{Yield} &= \Pr(X > LSL) = \Phi(3C_{PL}), \text{ or} \\ P(\text{NC}) &= \Phi(-3C_{PL}) \end{aligned} \quad (11)$$

Given value of C_{PU} or C_{PL} , the corresponding fraction of nonconforming in ppm is

$$\begin{aligned} \text{NCPPM} &= 10^6 \times \Phi(-3C_{PU}) \text{ or} \\ \text{NCPPM} &= 10^6 \times \Phi(-3C_{PL}) \end{aligned} \quad (12)$$

In practice, sample data must be collected in order to calculate these indices. The natural estimators of C_{PU} and C_{PL} are respectively defined as:

$$\hat{C}_{PU} = \frac{USL - \bar{X}}{3S} \text{ and } \hat{C}_{PL} = \frac{\bar{X} - LSL}{3S} \quad (13)$$

For normally distributed processes, Pearn and Chen [14] showed that $\tilde{C}_{PU} = b_f \cdot \hat{C}_{PU}$ and $\tilde{C}_{PL} = b_f \cdot \hat{C}_{PL}$ with $f = n - 1$ and $b_f = \sqrt{\frac{2}{f}} \cdot \frac{\Gamma[f/2]}{\Gamma[(f-1)/2]}$ are the uniformly minimum variance unbiased estimators (UMVUEs) of C_{PU} and C_{PL} , respectively. Based on the UMVUEs, $\tilde{C}_{PU}$, and $\tilde{C}_{PL}$, Lin and Pearn [15] provided testing procedures and efficient SAS computer programs for practitioners to assess processes with one-sided specification limit.

Summary and Related Topics

In this article, PCIs dedicated to the measurement of the yield of normally distributed processes with two-sided specification limits as well as one-sided specification limit are discussed. The yield measure formulas based on C_{pk} , C_{pm} , C_{pmk} , S_{pk} , C_{PU} , and C_{PL} are all given. The corresponding upper bounds of NCPPM for various values of C_{pk} , C_{pm} , and C_{pmk} as well as the corresponding NCPPM for various S_{pk} values are tabulated. For non-normal situation, the technique of non-normal quantile estimation is the most common method in use today for modifying PCIs [16, 17].

Control Charts and Process Capability

Introduction

Statistical process control (SPC) charts play a very important role in the determination of process capability. Process capability index measurements are meaningless when calculated from an unstable, out-of-control process. The very definition of “process capability” hints at long-term process quality, and given that process data taken from an out-of-control process in no way indicates what the process is capable of producing in terms of quality product, no valuable predictive information can be gleaned from this type of data. Therefore, it is absolutely imperative that statistical control be achieved *via* the use of appropriate **control charts** before process capability indices are calculated. Process capability indices and control charts should be considered an inseparable pair of **benchmarking** tools for the quality conscious enterprise.

Although many indices have been introduced in the literature to represent process capability from various perspectives (see Kotz and Lovelace [1]), the original C_p and C_{pk} indices remain the dominant choice among quality professionals, along with the second generation index C_{pm} , which contains an additional component for quantifying deviations from target. These indices are defined as

$$C_p = \frac{USL - LSL}{6\sigma} = \frac{d}{3\sigma} \quad (1)$$

$$C_{pk} = \min\left(\frac{USL - \mu}{3\sigma}, \frac{\mu - LSL}{3\sigma}\right) = \frac{d - |\mu - M|}{3\sigma} \quad (2)$$

and

$$C_{pm} = \frac{USL - LSL}{6\tau} = \frac{USL - LSL}{6\sqrt{\sigma^2 + (\mu - T)^2}} \quad (3)$$

where $USL - LSL$ is the allowable tolerance range of the process, $d = (USL - LSL)/2$ is the half-interval width, $M = (USL + LSL)/2$ is the midpoint of the specification interval, and τ is the standard deviation about the target.

A significant portion of the theoretical research dedicated to process capability indices has focused on

those index estimators that utilize a pooled estimator of process variance of the form

$$s = \frac{\sum_{i=1}^n (X_i - \bar{X})^2}{n - 1} \quad (4)$$

Estimators incorporating this pooled estimator are preferred by statisticians because of their superior and more tractable statistical properties, as compared to those containing an unpooled variance estimator (which utilizes subsample data from a control chart). (More details concerning the sampling distributions, **moments**, **confidence intervals**, etc. for the indices using the **pooled variance** estimator may be found in Kane [2], Kocherlakota [3], Kotz and Johnson [4], Boyles [5], Kotz and Johnson [6], Chou and Owen [7], Nagata and Nagahata [8], Chou *et al.* [9], Bissell [10], Pearn *et al.* [11], Chan *et al.* [12], Kushler and Hurley [13] and Johnson [14], among others.)

The use of index estimators containing s , however, does not promote or encourage the use of control charts to check for process stability, and requires a second sample over and above the data collected on these charts. Therefore, data collected in subsamples from an in-control SPC chart, most likely an $\bar{X} - R$ or $\bar{X} - s$ chart, is preferred in practice for index estimation. Juran and Gryna [15] termed this the *control chart method*, and it is the only technique for process capability estimation that provides a means to check for statistical control. In this case, σ is estimated from the in-control chart for the process by either

$$\hat{\sigma}_R = \frac{\bar{R}}{d_2} \quad (5)$$

or

$$\hat{\sigma}_s = \frac{\bar{s}}{c_4} \quad (6)$$

where $\bar{R}$ is the average subsample range, $\bar{s}$ is the average subsample standard deviation, and d_2 and c_4 are coefficients which are tabulated in numerous statistical **quality control** texts (see, e.g., Montgomery [16]). These estimators relate the process within-subgroup range (or standard deviation) to the sample standard deviation for normal processes.

This article will focus on the significant work published to date on process capability indices estimated using subsamples, as is the procedure when

2 Control Charts and Process Capability

using control chart data for index estimation, and the determination of optimal control chart parameters for quality programs that use capability indices as the primary measure of process status. Only by a thorough understanding of the statistical characteristics of the subsample index estimators can we effectively use control charts and process capability indices together for process benchmarking and improvement.

Control Chart Performance and Capability Indices

The first definitive examination of control chart performance and its effect on capability estimation was performed by Porter and Oakland [17], who studied the effect of process shifts on control chart performance for a given C_{pk} and subsample size (n). They considered the general case of a process mean shift of $k\sigma$, such that the upper 3σ tail of the distribution just touches the upper specification limit (USL) and 99.73% of the sample means are below the upper control limit. In this case, $k = 6/\sqrt{n}$ and C_{pk} can be redefined in terms of k

and n :

$$C_{pk} = \frac{USL - \mu}{3\sigma} = \frac{k\sigma + \sigma}{3\sigma} \\ = 1 + \frac{k}{3} = 1 + \frac{2}{\sqrt{n}} \quad (7)$$

From this definition, the probability of getting a sample mean outside the control limits on the $\bar{X}$ chart from the first sample after the shift, P_1 , can be calculated for a given C_{pk} and **sample size** (n). Table 1 (from Porter and Oakland [17]), gives the probability (P_1) for various values of C_{pk} and n . This table illustrates that a high C_{pk} value has a significant effect upon the probability of detecting a process shift.

Table 1 illustrates the significant threshold of $C_{pk} = 2$; at or above this capability level and for subgroup sizes of 2 or more, the probability of finding a sample mean above the control limit after a process shift is higher than 0.89, with a resulting **average run length** (ARL) of approximately 1. Therefore, it is very likely that a shift in the process mean of size $6\sigma/\sqrt{n}$ will be detected on the first sample taken after the shift. This is also shown graphically, for $n = 2$ to 8, in Figure 1.

Table 1 Probability of detecting a point outside the control limits when the first sample is taken after a process shift to the USL^(a)

Table 2 (also from Porter and Oakland [17]) contains the ARL to an action point (ARL(A)) from the P_1 probabilities for various values of C_{pk} and n . Following the pattern seen in Table 1, large C_{pk} values allow for relatively small required subsample sizes in order to achieve desirably low ARLs. The poorer the process capability, the larger the subsample size must be in order to keep the ARL acceptably low.

Of practical interest is the required value of C_{pk} for a given value of n , such that $P_1 \geq 0.9987$. These

values are provided in Table 3. It can be seen that for the smaller subgroup sizes, C_{pk} must be greater than 2 in order to achieve $P_1 \geq 0.9987$. As C_{pk} decreases, larger subgroup sizes are needed in order to increase the probability of process shift detection.

Control charts may also be optimized for the specific purpose of monitoring process quality using capability indices. More and more often, organizations are using capability indices themselves to define current process status. They are also utilized as a bridge between current process performance as monitored by SPC charts and the product design specifications. Therefore, control chart parameters may be optimized to control to a specific minimum index requirement. Wu *et al.* [18] developed an algorithm for designing the $\bar{X} - s$ chart that aligns the in-control and out-of-control parameters of the charts with a required value of C_{pk} . Specifically, the charts are designed so that when C_{pk} declines below a minimum threshold, the $\bar{X} - s$ chart will give a signal within a short period of time.

As originally shown by Kane [2], a single C_{pk} value will correspond to an infinite number of (μ, σ) pairs for the process distribution, therefore corresponding to an infinite number of possible shifts in the mean (δ_μ) or standard deviation (δ_σ) of the process. Also, since C_{pk} compares the allowable design

4 Control Charts and Process Capability

specification range to the center and spread of the process, it can serve as a link between the control charts and the process specifications. When the process shifts by δ_μ , as indicated on the $\bar{X}$ chart, or by δ_σ , as indicated on the s chart, C_{pk} will decrease. If C_{pk} decreases to some critical level, say $C_{pk,d}$, the defective rate will increase to an undesired level, and the process should be stopped. An optimally designed $\bar{X} - s$ chart will have a large in-control ARL, ARL_0 , so that the false alarm rate is very small, as well as a small out-of-control ARL, ARL_d , so that out-of-control conditions are detected quickly. The Wu *et al.* [18] modification to these charts is based upon the following optimization model:

Minimize : n

Subject to : $arl_0 \geq ARL_0$ (at $C_{pk} = c_{pk,0}$) (8)

$arl_d \leq ARL_d$ (at $C_{pk} = c_{pk,d}$) (9)

where arl_0 and arl_d are the actual in-control and out-of-control ARLs, respectively. The optimal design of the $\bar{X} - s$ chart is dependent upon the maximum allowable probability of type I error, α , and is composed of two elements, $\alpha_{\bar{X}}$ and α_s (the type I error probabilities for the $\bar{X}$ chart and s chart, respectively). For a specific shift pattern $(\delta_\mu, \delta_\sigma)$, the out of control $C_{pk,d}$ may be calculated as

$$C_{pk,d} = \frac{USL - (\mu_0 + \delta_\mu \sigma_0)}{3\delta_0 \sigma_0} \quad (10)$$

Note that each shift pattern is actually determined by δ_μ , since δ_σ is dependent upon δ_μ for a given

Table 3 Required C_{pk} for a given sample size, n , and process mean shift, $k\sigma$, to satisfy the requirements $P_1 \geq 0.9987^{(a)}$

value of $C_{pk,d}$. The mean shift δ_μ can vary from 0 to $\delta_{\mu,\max}$, and $\delta_{\mu,\max}$ can be determined as

$$\delta_{\mu,\max} = \frac{USL - \mu_0 - 3c_{pk,d}\sigma_0}{\sigma_0} \quad (11)$$

by setting δ_σ to its minimum value of 1.

There are an infinite number of control limit patterns $(LCL_{\bar{X}}(\alpha_{\bar{X}}), UCL_{\bar{X}}(\alpha_{\bar{X}}), UCL_s(\alpha_s))$ for a given sample size n , and a particular sample size is considered feasible per the optimization model given above if the corresponding $arl_d(\alpha_{\bar{X}}^*) \leq ARL_d$, where $\alpha_{\bar{X}}^*$ is the optimal value of $\alpha_{\bar{X}}$ associated with the shortest $arl_d(\alpha_{\bar{X}}^*)$ among all $arl_d(\alpha_{\bar{X}})$.

The Wu *et al.* [18] procedure for checking the feasibility of a sample size n is as follows:

1. Calculate the required value of α as

$$\alpha = \frac{1}{ARL_0} \quad (12)$$

2. Calculate $\delta_{\mu,\max}$ by equation (11).
3. Determine the optimal $\alpha_{\bar{X}}^*$ within the range $0 < \alpha_{\bar{X}} < \alpha$. To accomplish this, for each given value of $\alpha_{\bar{X}}$ determine:
 - (a) The corresponding α_s by

$$\alpha_s = \frac{\alpha - \alpha_{\bar{X}}}{1 - \alpha_{\bar{X}}} \quad (13)$$

- (b) The associated control limits using the equations

$$LCL_{\bar{X}} = \mu_0 - z \times \frac{\sigma_0}{\sqrt{n}} \quad (14)$$

$$UCL_{\bar{X}} = \mu_0 + z \times \frac{\sigma_0}{\sqrt{n}} \quad (15)$$

and

$$UCL_s = \sigma \sqrt{\frac{\chi_{\alpha_s, n-1}^2}{n-1}}, LCL_s = 0 \quad (16)$$

- (c) The out-of-control ARL $arl_d(\alpha_{\bar{X}})$ using

$$arl_d(\alpha_{\bar{X}}) = arl_d(LCL_{\bar{X}}(\alpha_{\bar{X}}), UCL_{\bar{X}}(\alpha_{\bar{X}}),$$

$$UCL_s(\alpha_s))$$

$$= \int_0^{\delta_{\mu,\max}} arl'_d(\delta_\mu, \delta_\sigma) f(\delta_\mu) d\delta_\mu$$

$$= \int_0^{\delta_{\mu,\max}} arl'_d(\delta_\mu, \delta_\sigma(\delta_\mu)) f(\delta_\mu) d\delta_\mu \quad (17)$$

where $f(d_\mu)$ is the **probability density function** of δ_μ .

4. If $arl_d(\alpha_{\bar{X}}^*) \leq ARL_d$, the sample size is feasible.

Step 3 of the above procedure sets the optimal allocation of the detection **power** between the $\bar{X}$ and s charts that results in the minimum out of control arl_d .

Caution is urged when considering this process control approach since process control charts should *control* to the inherent variation range of the process and not to process design specifications. The standard rule of thumb in process control is: "Don't put process specifications on a control chart." By controlling to a process capability index value, which contains the process specifications, you are controlling to the specs.

Confidence Intervals of Process Capability Indices for Subgrouped Data

The waters of statistical understanding are still a bit murky when it comes to capability indices and control chart data. For example, there are currently no confidence intervals other than tables developed *via* bootstrapping for estimators containing $\hat{\sigma}_R$. In this case, Li *et al.* [19] developed lower confidence limits for C_p using $\hat{\sigma}_R$. Noting that a $100(1 - \alpha)\%$ lower confidence limit on C_p , c_o , satisfies $\Pr(C_p \geq c_o) = \alpha$, then

$$\Pr(C_p \geq c_o) = \Pr\left\{\frac{C_p}{\hat{C}_p} \geq \frac{c_o}{\hat{C}_p}\right\} = \Pr\left\{\frac{R}{\sigma d_2} \geq \frac{c_o}{\hat{C}_p}\right\} = \alpha \quad (18)$$

or

$$\begin{aligned} \Pr\left\{\frac{\bar{R}}{\sigma d_2} \leq \frac{c_o}{\hat{C}_p}\right\} &= \Pr\left\{R' \leq \frac{d_2 c_o}{\hat{C}_p}\right\} \\ &= \Pr\left\{\frac{\sqrt{v} R'}{c} \leq \frac{\sqrt{v} d_2 c_o}{c \hat{C}_p}\right\} \\ &\cong \Pr\left\{\chi_v \leq \frac{\sqrt{v} d_2 c_o}{c \hat{C}_p}\right\} = 1 - \alpha \end{aligned} \quad (19)$$

where $R' = R/\sigma$. So,

$$\frac{\sqrt{v} d_2 c_o}{c \hat{C}_p} = \chi_{v, 1-\alpha} \quad (20)$$

so that

$$c_o = \frac{c \hat{C}_p}{\sqrt{v} d_2} \sqrt{\chi_{v, 1-\alpha}^2} \quad (21)$$

Table 4 (from Li *et al.* [19]) gives the ratio values of $c_o/\hat{C}_p$ for $m = 1, 5, 10, 20, 30$ and $n = 3$ to 10, where data is collect in m subgroups of size n each.

Hypothesis Tests Based on m Subgroups of Size n Each

Control chart (subsample) data may also be used to test hypotheses concerning process capability. Typically, hypothesis tests of the general form

$$\begin{aligned} H_0: & \text{The process is not capable} \\ H_1: & \text{The process is capable} \end{aligned}$$

are of interest when benchmarking a process's ability to meet product specifications. Using a standard **hypothesis testing** procedure, the degree of difference between the estimated capability index value and the true or hypothesized capability (as defined by a minimum capability requirement) is determined. To accomplish this, an index value is estimated, compared to a lower index bound c_o , then the so-called p value is computed, which refers to the actual risk of incorrectly concluding that the process is capable for a particular test. For the C_p index, the hypotheses are

$$\begin{aligned} H_0: & C_p \leq c_o \\ H_1: & C_p > c_o \end{aligned} \quad (22)$$

where c_o is the standard minimal criteria of C_p for a particular process. The hypotheses for other indices follow the same format.

Table 4 Maximum values of the ratio $c_o/\hat{C}_p$

Subgroup size, n	Number of subgroups (m)				
	1	5	10	20	30
3	0.255	0.631	0.735	0.811	0.845
4	0.369	0.697	0.783	0.845	0.873
5	0.443	0.735	0.811	0.865	0.890
6	0.494	0.760	0.829	0.879	0.901
7	0.533	0.779	0.843	0.888	0.908
8	0.562	0.793	0.853	0.895	0.914
9	0.586	0.804	0.861	0.901	0.919
10	0.605	0.813	0.867	0.906	0.923

C_p

While Kane [2] provided the critical hypothesis testing protocol for C_p when a single sample is used, Kirmani *et al.* [20] developed the critical value for the hypothesis test using subgroups. They used the estimator

$$\hat{C}_p^* = \frac{(USL - LSL)d_p}{6} \quad (23)$$

where

$$d_p = \sqrt{\frac{m(n-1)-1}{m(n-1)}} \times \frac{\varepsilon_{m(n-1)-1}}{s_p} \quad (24)$$

with constant

$$\varepsilon_k = \sqrt{\frac{2}{k}} \times \left[\frac{\Gamma(k+1)/2}{\Gamma(k/2)} \right] \quad (25)$$

C_{pk}

Lin and Sheen [21] developed a hypothesis testing regimen for C_{pk} for the case where process measurements are collected in subgroups from statistical control charts, and assuming the data were collected as a sequence of independent samples. They applied Hamaker's approximation so that the testing procedure can be adequately derived from a **normal distribution**, avoiding the more complicated sampling distributions of $\hat{C}_{pk(R)}$ and $\hat{C}_{pk(s)}$. The procedure provides p values for a given estimate of C_{pk} , which can then be used to evaluate the hypotheses. Subgrouped quality control data is typically collected on an $\bar{X} - R$ or $\bar{X} - s$ control chart pair, where the process standard deviation, σ , is estimated by either $\bar{R}/d_2$ or $\bar{s}/c_4$ as in equations (1) and (2). The coefficients d_2 and c_4 are added to eliminate **bias** within these estimators. $\hat{C}_{pk(R)}$ and $\hat{C}_{pk(s)}$ are the estimators of C_{pk} from the two pairs of charts, respectively.

When the process standard deviation is known, $3\sqrt{mn}\hat{C}_{pk(s)}$ is distributed as $N(3\sqrt{mn}C_{pk}, 1)$. Defining the observed value of $\hat{C}_{pk(R)} = W_R$, the p value can be computed as

$$p \text{ value} = \sup_{C_{pk} \leq C} \Pr\{\hat{C}_{pk(R)} \geq W_R | m, n\} \\ = \Pr\{Z \geq \theta_R\} \quad (26)$$

where

$$\theta_R = \left[\frac{3\sqrt{mn}(W_R - C)}{\sqrt{1 + 9nd_3^2 W_R^2 / d_2^2}} \right] \quad (27)$$

In similar fashion for the $\bar{X} - s$ chart estimate of C_{pk} , define $\hat{C}_{pk(s)} = W_s$. From this, the p value can be computed as

$$p \text{ value} = \sup_{C_{pk} \leq C} \Pr\{\hat{C}_{pk(s)} \geq W_s | m, n\} \\ = \Pr\{Z \geq \theta_s\} \quad (28)$$

where

$$\theta_s = \left[\frac{3\sqrt{mn}(W_s - C)}{\sqrt{1 + 9nc_5^2 W_s^2 / c_4^2}} \right] \quad (29)$$

C_{pm}

Hypothesis testing for C_{pm} is a bit tricky, and Carlsson [22] feels that tests of hypothesis concerning deviation from the target and tests concerning variation about the target cannot be tested separately. However, Chan *et al.* [12] developed a hypothesis testing procedure for their C_{pm} estimator, which is based on a single sample. The power of this procedure has not been tested. To date, no technique has been presented for hypothesis testing on C_{pm} with subsample data.

Conclusion

Process capability indices are used to measure the long-term ability of a process to manufacture product within specification. They must be estimated from stable (i.e., in-control) process data; otherwise, their values have no long-term implications for process performance. This stability must be assured *via* a statistical control chart, thus in practical terms control charts and process capability indices should be used as a pair. It is hoped that research will continue into the statistical characteristics, effects of subsample size, and practical implementation issues of process capability indices estimated from subsample, control chart data.

Process Capability Indices for Multiple Stream Processes

Introduction

Separate process streams are created in manufacturing when the flow of parts is divided into several presumably identical paths. This split in production occurs when an operation has different molds, spindles, lines, stations, lines, fixtures, or pallets. Presumably, the quality of parts produced by each stream is identical but, in practice, there are often substantial differences between streams. The capability index introduced in this article may be applied when a measure of capability is desired for the combined output of all streams.

The C_{pk} Index

As in all capability studies, the first prerequisite is to verify that each process stream is in a reasonably good state of statistical control (*see Control Charts and Process Capability*). The output from each stream may have a different average and/or standard deviation, but every stream must have a stable, predictable output.

For example, an injection-molding operation utilizes a four-cavity die to produce a plastic part. Through the use of **control charts**, each cavity demonstrates good stability for the inner diameter (i.d.) of the part being molded, but the output of hole size varies considerably from cavity to cavity, as is illustrated in Figure 1.

After the parts are molded, they fall down a chute into a common container, which is then shipped to a customer. What should the customer who receives this shipment – which contains a mixture of parts from all four cavities – expect in terms of parts meeting the specification requirements for hole size?

One popular metric for assessing capability is called the C_{pk} index [1], which is defined in equations (1–3). Here, μ is the process mean, σ is the process standard deviation, LSL is the lower specification limit for the feature being studied, and USL is its upper specification limit (*see Control Charts for*

Figure 1 Distributions of hole size for each of four cavities (labeled 1–4)

the Mean).

$$C_{pk} = \text{minimum}(C_{pl}, C_{pu}) \quad (1)$$

$$C_{pl} = \frac{\mu - LSL}{3\sigma} \quad (2)$$

$$C_{pu} = \frac{USL - \mu}{3\sigma} \quad (3)$$

If only an LSL is given for the feature being studied, then C_{pk} equals C_{pl} . Conversely, when just a USL is provided, C_{pk} equals C_{pu} .

When the process output is close to a **normal distribution**, the percentage of parts below the LSL, p_{LSL} , is determined with equation (4), where $\Phi(\cdot)$ is the cumulative distribution function of the standard normal distribution (with $\mu = 0$ and $\sigma = 1$) [2]. For example, $\Phi(0)$ equals 0.50000 (50%), $\Phi(2)$ equals 0.97725, and $\Phi(3)$ equals 0.99865. In the spreadsheet program Excel, $\Phi(2)$ corresponds to the statistical function NORMSDIST(2), which returns the value of 0.97725.

$$p_{LSL} = 1 - \Phi(3C_{pl}) \quad (4)$$

Likewise, the percentage of parts above the USL, p_{USL} , is found with equation (5).

$$p_{USL} = 1 - \Phi(3C_{pu}) \quad (5)$$

The total percentage of nonconforming parts, p_T , is then computed as demonstrated in equation (6).

$$p_T = p_{LSL} + p_{USL} \quad (6)$$

Typically, because the output for each process stream will have a different mean and standard deviation, each stream will have different C_{pk} , p_{LSL} , and p_{USL} values.

2 Process Capability Indices for Multiple Stream Processes

Past Attempts

When faced with differences between process streams that cannot be easily corrected, some practitioners compute the C_{pk} index for all streams and then report just the highest value to customers. This practice is deceptive as it would cause customers to believe they are purchasing a higher level of quality than what they will actually receive.

To avoid misleading customers, other practitioners go to the opposite extreme and report just the lowest C_{pk} index of all the individual streams. Doing so means the customer will receive at least this quality level because the percentages of conforming parts are greater for the outputs from all the other streams. However, if there are large differences between the streams, reporting results for only the worst stream will make the manufacturer's overall quality level look much poorer than it really is.

A third approach has been to report an overall capability index by averaging the C_{pk} indices for the individual streams. To demonstrate why this technique is invalid, suppose an operation has just two process streams; the output of the first stream has a C_{pk} of 2.00 while the output of the second has a C_{pk} of 0.00. The average of these two C_{pk} indices is 1.00 $[(2.00 + 0.00)/2 = 1.00]$.

From equation (1), a C_{pk} index of 1.00 means that both C_{pl} and C_{pu} must also be at least 1.00. Then, from equations (4) and (5), neither p_{LSL} nor p_{USL} can be greater than 0.135%. Thus, a C_{pk} index of 1.00 implies that p_T for this shipment is at most 0.27%.

However, the process stream with a C_{pk} index of 2.00 is producing essentially 0.0% nonconforming parts (because C_{pu} and C_{pl} are both equal to, or greater than, 2.00, both p_{LSL} and p_{USL} are very close to 0). On the other hand, the second stream is generating at least 50% nonconforming parts (with either C_{pu} or C_{pl} equal to 0.00, either p_{LSL} or p_{USL} equals 0.5000 while the other is equal to, or less than, 0.5000).

Assuming both streams produce an equal number of parts in a given shipment, there will be an overall average of at least 25% nonconforming parts $(0 + 50\%)/2$, which is much larger than the 0.27% maximum expected from a shipment with a C_{pk} rating of 1.00. Thus, reporting a C_{pk} index of 1.00 for a shipment containing a mixture of the outputs from these two process streams would falsely imply a much higher quality level than will be received by the customer.

Table 1 Percentage nonconforming for each cavity

Cavity, i	$p_{i,LSL}$	$p_{i,USL}$
1	0.001	0.004
2	0.000	0.008
3	0.015	0.000
4	0.000	0.000
Sum for all four cavities	0.016	0.012
Average percentage nonconforming	0.004	0.003

Computing the Average C_{pk} Index

To correctly calculate the "average" C_{pk} of the combined output from several process streams, the percentage of out-of-specification parts produced by each stream should first be computed. For the four process streams of the plastic injection-molding operation mentioned earlier, these calculations generate the results displayed in Table 1. Here, i represents the cavity number, $p_{i,LSL}$ is the expected percentage of parts with hole diameters below the LSL for the i th cavity, while $p_{i,USL}$ is the expected percentage of parts with hole diameters above the USL for the i th cavity.

The individual percentages of parts with hole sizes below the LSL for each of these four cavities sum to a total of 0.016, or 1.6%, as is seen in the second-last row of Table 1. This total is then divided by four – in general, q , the number of process streams – to come up with 0.004 $(0.016/4)$. (This calculation assumes each of the four cavities contributes 1/4 of the total production of parts.) This last value is labeled $\bar{p}_{LSL}$, which represents the expected average percentage of parts with hole diameters below the LSL for the combined output of the four cavities. Equation (7) demonstrates this calculation for the injection-molding example.

$$\bar{p}_{LSL} = \frac{\sum_{i=1}^q p_{i,LSL}}{q} = \frac{\sum_{i=1}^4 p_{i,LSL}}{4} = \frac{0.016}{4} = 0.004 \quad (7)$$

The above average is an estimate of the percentage of parts below the LSL that the customer will receive, and is thus an indication of the process's ability to mold parts with hole sizes above the lower specification limit.

In a similar manner, an estimate of the expected average percentage of parts produced by this process

with hole diameters above the USL is 0.3%, as is shown by equation (8).

$$\bar{p}_{USL} = \frac{\sum_{i=1}^4 p_{i,USL}}{4} = \frac{0.012}{4} = 0.003 \quad (8)$$

The C_{pl} value, labeled $\bar{C}_{PL}$, corresponding to a given $\bar{p}_{LSL}$ is found by rearranging equation (4) to derive equation (9). The $\Phi^{-1}(\cdot)$ operator is the inverse of the $\Phi(\cdot)$ operator previously defined for equation (4). In Excel, $\Phi^{-1}(0.97725)$ corresponds to the statistical function NORMSINV(0.97725), which returns the value of 2.0000.

$$\bar{C}_{PL} = \frac{\Phi^{-1}(1 - \bar{p}_{LSL})}{3} \quad (9)$$

In the four-cavity die example, the $\bar{p}_{LSL}$ of 0.004 is associated with a $\bar{C}_{PL}$ value of 0.88, as is shown in equation (10).

$$\bar{C}_{PL} = \frac{\Phi^{-1}(1 - 0.004)}{3} = \frac{2.652}{3} = 0.88 \quad (10)$$

In a similar manner, equation (11) demonstrates how the $\bar{C}_{PU}$ value corresponding to a $\bar{p}_{USL}$ of 0.003 is calculated to be 0.92.

$$\begin{aligned} \bar{C}_{PU} &= \frac{\Phi^{-1}(1 - \bar{p}_{USL})}{3} = \frac{\Phi^{-1}(1 - 0.003)}{3} \\ &= \frac{2.748}{3} = 0.92 \end{aligned} \quad (11)$$

The average C_{pk} index is then defined as shown in equation (12).

$$\begin{aligned} \text{Average } C_{pk} &= \text{minimum}(\bar{C}_{PL}, \bar{C}_{PU}) \\ &= \text{minimum} \left[\frac{\Phi^{-1}(1 - \bar{p}_{LSL})}{3}, \frac{\Phi^{-1}(1 - \bar{p}_{USL})}{3} \right] \end{aligned} \quad (12)$$

Using the numbers from the previous example, an estimate of the average C_{pk} index for the hole diameters of parts produced by this four-cavity die molding process is computed in equation (13) to be 0.88.

$$\text{Average } C_{pk} = \text{Minimum}(0.88, 0.92) = 0.88 \quad (13)$$

Because this index is quite a bit less than 1.00, the combined output of the four cavities is *not* capable of consistently producing at least 99.73% conforming parts as far as hole size is concerned. In fact, it is producing 0.4% below the LSL and 0.3% above the USL, for a total of 0.7% nonconforming parts, which equates to 99.3% conforming parts. This is the quality level a customer would expect from a process having a traditional C_{pk} rating of 0.88.

Although the average C_{pk} index would be reported to customers, the individual cavity results are used to target process improvement efforts. In the four-cavity die example, cavity three has the largest percentage of parts (1.5%) with hole diameters below the LSL. Because it has no parts with holes above the USL, the initial capability improvement effort for this process should focus on increasing the average output of cavity three (refer back to Figure 1).

Average C_{pk} for Attribute Data

The average C_{pk} index can also be used when assessing the combined capability of several process streams that are generating attribute-type data (*see Measurement Systems Analysis, Attribute*), as this next example demonstrates.

Dough for frozen pizzas is arranged in six rows on a conveyor. The conveyor then moves under several dispensing stations that deposit various vegetables, meats, sauces, and cheeses on the dough. At the end of this line, the pizzas coming off each row are checked to see if the ingredients are evenly distributed over the face of the pizza. Those with an unacceptable ingredient distribution are rejected. After achieving stability for each of the six rows, their rejection rates are estimated and summarized in Table 2.

The average C_{pk} index for the combined output of these six process streams is computed by first determining the average percentage of pizzas that do not satisfy the appearance requirement, as seen in equation (14).

$$\bar{p} = \frac{\sum_{i=1}^6 p_i}{6} = \frac{0.000072}{6} = 0.000012 \quad (14)$$

4 Process Capability Indices for Multiple Stream Processes

Table 2 Rejection rate for each row

Row, i	p_i
1	0.000016
2	0.000003
3	0.000022
4	0.000012
5	0.000005
6	0.000014
Sum	0.000072
Average	0.000012

The average C_{pk} index is then computed as displayed in equation (15).

$$\text{Average } C_{pk} = \frac{\Phi^{-1}(1 - \bar{p})}{3} = \frac{4.224}{3} = 1.41 \quad (15)$$

Given a C_{pk} goal of 1.33, the combined output of these six rows demonstrates very good capability for meeting the appearance requirement.

Summary

The average C_{pk} index provides a method for assessing the outgoing quality of a mixture of outputs from similar process streams. This metric does not require

the outputs from all streams to be centered at the same value nor have the same process spread, which is important because, in most cases, they will not. In addition to part features (with either unilateral or bilateral specifications) whose measurements generate variable-type data, this index applies equally well to features characterized by attribute-type data.

Measurement Systems Analysis, Attribute

Introduction

Methods for assessing the capability of a quantitative or continuous **measurement system** are well documented and include the tabular method and the analysis of variance approach. When the measurement system involves attribute data, the standard quantitative methods are not appropriate. An attribute gauge measurement system is one in which the parts or objects under study are placed into one of two or more possible categories. The classification of the part is the measurement of interest in an attribute measurement system. Several commonly used statistics for “appraiser agreement” and attribute gauge repeatability and reproducibility (GRR) are presented.

Kappa Statistics

Two Appraisers

The κ statistic suggested by [1] measures the agreement between two appraisers (raters, judges) when evaluating or rating the same item. Cohen’s kappa statistic is given by

$$\kappa = \frac{p_o - p_e}{1 - p_e} \quad (1)$$

where p_o represents the observed proportion of agreement between appraisers and p_e represents the expected proportion of agreement due to chance. Table 1 illustrates a typical 2×2 table with two appraisers (X, Y) and two categories (pass, fail). The values a, b, c, d represent the number of times the appraisers agreed (a, d) and disagreed (b, c).

Table 1 Standard summary for two appraisers and two categories

		Ratings by appraiser X		Totals
		Pass	Fail	
Ratings by appraiser Y	Pass	a	b	n_1
	Fail	c	d	n_2
	Totals	m_1	m_2	N

Using the notation from Table 1, the observed proportion of agreement for this binary system is $p_o = (a + d)/N$ and the expected proportion of agreement due to chance is $p_e = (m_1 n_1 + m_2 n_2)/N^2$. If there is perfect agreement between appraisers, then $\kappa = 1$. If all observed agreement is due to chance, then $\kappa = 0$. κ will be negative if the agreement is less than what would be expected purely by chance. Cohen’s κ can be calculated for any two appraisers and is a single value summarizing the quality of measurements.

More than Two Appraisers

The κ statistic suggested by [2] is a variant to Cohen’s kappa statistic which takes into account more than two appraisers measuring the same number of items. Fleiss [2] suggested that the proportion of agreeing pairs be used to determine the degree of agreement among appraisers. Specifically, p_o and p_e are formulated to account for more than two appraisers by averaging the proportion of agreement for each pair of appraisers. Following the notation of [2], suppose there are N parts, n ratings per part, and k possible ratings (categories). Furthermore, suppose there are n_{ij} appraisers who will assign the i th part to the j th category. The proportion of agreeing pairs out of all possible pairs of category assignments is

$$p_i = \frac{1}{n(n-1)} \sum_{j=1}^k n_{ij}(n_{ij} - 1) \quad (2)$$

The average of all p_i ’s ($i = 1, \dots, N$) can be used as the measure for overall agreement,

$$p_o = \frac{1}{N} \sum_{i=1}^N p_i = \frac{1}{Nn(n-1)} \left(\sum_{i=1}^N \sum_{j=1}^k n_{ij}^2 - Nn \right) \quad (3)$$

If the extent of agreement is purely by chance, then we can expect the average proportion of agreement to be

$$p_e = \sum_{j=1}^k p_j^2 \quad (4)$$

The quantities given in equations (3) and (4) are used to calculate κ given in equation (1). The resulting κ statistic is often referred to as *Fleiss’s kappa*

statistic. It is of interest to note that Fleiss's kappa is useful for determining which category level(s) the appraisers (raters) are in relative agreement on, as well as the one(s) in which they do not have a common understanding (disagreement). In practice, this makes it easier to target remedial training or rewrite operational definitions of the categories in order to improve the measurement system. For more information on κ with multiple appraisers see [2–3] and [4].

Limitations of κ Statistics

κ cannot measure the degree of agreement or the size of disagreement between the two appraisers. Also, the value of κ can be misleading. For example, it would seem intuitive that a large value of p_o (indicating high agreement between appraisers), would result in a large value of κ . But, the resulting κ could be misleadingly small if p_e happens to be a large value. To illustrate, consider the data displayed in Table 2.

In this hypothetical situation, we have $p_o = (80 + 5)/100 = 0.85$, a value indicating a high level of agreement between the appraisers. Next, $p_e = [(95)(80) + (5)(20)]/100^2 = 0.77$. As a result, $\kappa = 0.34$. Therefore, a large value of p_e can result in a small value of κ , even if the proportion of observed agreement between appraisers is quite large. This phenomenon is one of two paradoxes associated with κ (see [5] for details and illustrations of both paradoxes).

Summary of κ Statistics

Overall, the κ statistics are easy to calculate and are often reported in standard statistical software. The κ statistics presented in this section can be used for binary data or ratings with more than two categories. The statistics provide some measure of reproducibility for attribute measurement systems. A

measure of repeatability is possible if each appraiser rates each part more than once. Often, repeatability is of less importance than reproducibility in these situations since appraisers tend to give similar (if not the same) ratings to the same part; this results in a high level of repeatability.

There are several drawbacks associated with the use of κ statistics, one of which has been illustrated here. Other problems with the use of Cohen's κ are that it assumes that the two appraisers use the same rating scale. Although this is a desirable condition, there may be situations where one appraiser would use one rating scale (say 1–8) while the other uses a different rating scale (say 1–10). This situation may be appropriate when there is interest in quantifying the consistency of ratings for an appraiser who uses different rating scales. There have been several extensions of Cohen's κ including a weighted κ statistic, statistics for paired data and for situations where **covariate** information is available. See [2–7] for more details concerning drawbacks and alternative statistics for interrater agreement.

Intraclass Correlation

The intraclass correlation coefficient (ICC) measures the correlation among multiple measurements of the same item or part. ICC was developed as an alternative to Cohen's κ [8] and has been used to evaluate reproducibility due to different appraisers. (Note: ICC is sometimes referred to as the *intraclass* κ and could have been discussed in the section titled “Kappa Statistics” (see [9]).)

The intraclass correlation is the correlation between different measurements Y_{ij} and Y_{ik} taken on the i th part or object and can be calculated as

$$ICC = \frac{\text{Cov}(Y_{ij}, Y_{ik})}{\sqrt{\text{Var}(Y_{ij}) \cdot \text{Var}(Y_{ik})}} = \frac{\sigma_p^2}{\sigma_p^2 + \sigma_e^2} \quad (5)$$

σ_p^2 represents the variability between parts σ_e^2 represents the variability within a part or object. An ICC of 0 would indicate lack of consistency among appraisers. An ICC = 1 would indicate perfect consistency or perfect reliability. It should be noted that for continuous measurement systems, ICC can also be written in terms of GRR for a one-way analysis of variance (see **Variance Components; Gauge Repeatability and Reproducibility (R&R)**,

Table 2 Sample data for two appraisers and two categories

		Ratings by appraiser X		
		Pass	Fail	Totals
Ratings by appraiser Y	Pass	80	5	80
	Fail	15	5	20
	Totals	95	5	100

Variance Components in; Gauge Repeatability and Reproducibility (R&R) Studies, Misclassification Rates). One summary of GRR for a one-factor random model is

$$GRR = \frac{\sigma_e}{\sqrt{\sigma_p^2 + \sigma_e^2}} \quad (6)$$

We can then write $ICC = 1 - (GRR)^2$. Although the ICC can be used to provide a measure of reproducibility, complete distributional assumptions are necessary since it is estimated using random-effects models.

Binary Measurement Systems

Suppose the quality characteristic under study can assume only two possible values (pass/fail, go/no go, and 0/1). Initially, also assume there are only two appraisers. For this binary measurement system, the ICC could be written as (this is identical to the ϕ coefficient defined in [4])

$$\begin{aligned} ICC_b &= \frac{\text{Cov}(Y_{ij}, Y_{ik})}{\sqrt{\text{Var}(Y_{ij}) \cdot \text{Var}(Y_{ik})}} \\ &= \frac{P(Y_{i1} = 1, Y_{i2} = 1) - p_1 p_2}{\sqrt{p_1(1 - p_1) \cdot p_2(1 - p_2)}} \end{aligned} \quad (7)$$

where $Y_{ij} = 1$ represents a successful rating on the i th part by the j th appraiser. The estimates for p_1 , p_2 , and $P(Y_{i1} = 1, Y_{i2} = 1)$ are

$$\begin{aligned} \hat{p}_1 &= \frac{\sum_{i=1}^n Y_{i1}}{n}, \quad \hat{p}_2 = \frac{\sum_{i=1}^n Y_{i2}}{n}, \\ \hat{P}(Y_{i1} = 1, Y_{i2} = 1) &= \frac{\sum_{i=1}^n Y_{i1} Y_{i2}}{n} \end{aligned} \quad (8)$$

and n is the number of parts or items being measured.

If the binary measurement system has m appraisers ($m > 2$), then the recommendation by [10] and [11] (and summarized in [4]) involves averaging the ICC_b values for all pairs of appraisers. They also assume that $p_j = p$ for all appraisers (see [4] for more discussion).

Analytic Method for Estimating Bias and Repeatability

Gauge studies are carried out to determine the suitability of the measurement system for use in a particular application. The *analytic method* detailed in [12] provides estimates of bias and repeatability for an attribute gauge and involves approximating the naturally discrete distribution with a continuous distribution, namely the normal (or Gaussian) distribution. This method assumes there are multiple parts or objects to be measured and that each part is measured multiple times by a single appraiser or measuring device. Once measured, the part is classified as acceptable (a) or unacceptable (e.g., binary data). Furthermore, it is assumed that a “standard” or reference value is known or can be obtained for the quality characteristic of interest.

The analytic method has the following requirements [12]:

- There must be a known reference value for each part selected.
- At least eight parts are selected at equidistant intervals.
- The minimum and the maximum values must represent the range of the process.
- Each part is measured $m = 20$ times under identical conditions.
- The number of “accepts” (a) is recorded.
 - Smallest part must have no accepts ($a = 0$). (If this is not satisfied, smaller parts are selected until $a = 0$.)
 - The largest part must have all accepts ($a = 20$). (If this is not satisfied, then larger parts are selected until $a = 20$.)
 - The remaining six parts must have between 1 and 19 accepts, inclusive ($1 \leq a \leq 19$). (If this is not satisfied, more parts are selected over the range – the additional parts are selected at the midpoint between the parts that have already been measured.)

In the analytic approach, gauge bias and gauge repeatability are then estimated by calculating probabilities of acceptance using normal probability plotting (see **Probability Plots**) – a procedure first put forth by [13]. Reproducibility is not estimable since there is a single gauge measuring the parts. The accuracy of the bias and repeatability estimates has

been questioned since it depends on the normal approximation of discrete data. The authors in [14] propose an improved approach for estimating bias and repeatability. In their work, they provide an alternative statistical estimation procedure that takes advantage of modern computational capabilities.

Latent-Class Models

A promising approach to assessing an attribute measurement system – repeatability and reproducibility in particular – is the use of latent-class models. The latent variable in this case represents the true value of the part or object, and as the name implies, is unknown. For interrater agreement, the latent-class model approach assumes that a part being rated or judged belongs to one of two or more possible latent classes. For example, in a binary system there would be two latent classes, namely, pass/fail. The probability that a part receives a particular rating is assumed to be dependent upon the latent class to which the part truly belongs. The joint distribution of the ratings is represented by a latent-class model and consists of a mixture of distributions for the classes of the latent variable. For example, in a binary measurement system, the latent-class model would consist of a mixture of binomial distributions.

Binary measurement systems are commonly encountered in industrial practice. Boyles [15] describes an approach for this situation using latent-class models. Using the notation and method presented in [15], suppose there are p parts and n_i ratings (inspections) of the i th part. Let s_i represent the number of “pass” evaluations of the i th part, i.e. $s_i = \sum_{j=1}^n y_{ij}$, where y_{ij} represents the j th rating of the i th part. For a binary measurement system, let $y_{ij} = 1$ if the i th part receives a pass evaluation (rating) on the j th rating, and $y_{ij} = 0$ if the i th part does not receive a pass evaluation (fails) on the j th rating. The distribution of s_i consists of a mixture of binomial distributions, namely

$$\begin{aligned} P(s_i = s) &= E[P(s_i = s | \xi_i)] \\ &= \binom{n_i}{s} [\phi \theta_1^s (1 - \theta_1)^{n_i - s} \\ &\quad + (1 - \phi) \theta_0^s (1 - \theta_0)^{n_i - s}] \end{aligned} \quad (9)$$

where ξ_i represents the latent classes with $\xi_i = 1$ if the i th part is good and $\xi_i = 0$ if the i th part

is bad. It is assumed that parts in each category of ξ are homogeneous. As a result, for a given level of ξ_i , the joint ratings of the appraisers are assumed to be statistically independent. If the parts are randomly selected from a population of parts, $\phi = P(\xi_i = 1)$ represents material variation. Boyles [15] further denotes the variability due to the measurement system by

$$\theta_0 = P(y_{ij} = 1 | \xi_i = 0) \quad (10)$$

$$\theta_1 = P(y_{ij} = 1 | \xi_i = 1) \quad (11)$$

Therefore, θ_0 is the probability that a part passes when the part is bad and θ_1 is the probability that a part passes when the part is good. The misclassification rates are θ_0 and $1 - \theta_1$. θ_0 and θ_1 are considered the gauge parameters. Furthermore, it is assumed that $\theta_0 < \theta_1$, i.e., the probability that a good part is classified as good is greater than the probability that a good part is classified as bad. Under these conditions (which [15] refers to as the basic model), it can be shown that

$$\begin{aligned} \text{Var}(y_{ij}) &= [\phi \theta_1 (1 - \theta_1) + (1 - \phi) \theta_0 (1 - \theta_0)] \\ &\quad + (\theta_1 - \theta_0)^2 \phi (1 - \phi) \end{aligned} \quad (12)$$

It is desired that estimates be obtained for the gauge parameters (θ_0 , θ_1) and the material variation (ϕ). Maximum-likelihood estimates (MLEs) (see **Maximum Likelihood**) can be found using the expectation-maximization (EM) algorithm where the likelihood function from equation (9) is

$$L \propto \prod_{i=1}^p \{ \phi \theta_1^s (1 - \theta_1)^{n_i - s} + (1 - \phi) \theta_0^s (1 - \theta_0)^{n_i - s} \} \quad (13)$$

The resulting MLEs of (θ_0 , θ_1 , ϕ) provide information about the misclassification levels in the system. In addition, **confidence intervals** can be constructed on the misclassification rates (see [15], p. 225; **Gauge Repeatability and Reproducibility (R&R) Studies, Misclassification Rates**). The author in [15] goes on to demonstrate how the reproducibility can be examined using this modeling approach. Detailed information on latent-class models, their development, and applications can be found in [4, 9, 16–20].

Summary and Conclusions

Several commonly used measures of assessment for attribute data have been presented. Attribute GRR studies can be carried out using appraiser agreement statistics (κ statistics, intraclass correlation), the analytic method, and latent-class models. Each approach can provide some measure of reproducibility or repeatability as discussed. The analytic method also provides some measure of system bias.

Commonly used criteria such as the κ statistics provide only a single statistic to describe the capability of the entire system. The latent-class model approach provides a model that can be used to describe the gauge capability for a measurement system.

If summary statistics are to be used, the ICC is a better measure of interrater agreement than Cohen's κ statistic, if the underlying marginal distributions are identical across all appraisers.

The latent-class model approach is extremely useful for the evaluation of attribute measurement systems; in particular, binary (pass/fail) measurement systems. Reference [15] employs latent-class models to estimate misclassification rates for binary measurement systems under a model where a standard is given and a model when no standard is given. The author in [15] describes a method for estimating repeatability and reproducibility effects utilizing misclassification rates. The authors in [4] compare latent-class models with κ statistics and log-linear models. As they have noted, the latent-class model approach provides a model for the outcome of measurement system, whereas the κ statistics and intraclass correlation are statistics – one-number summaries that are supposed to describe an entire measurement system. The authors in [4] recommend the latent-class model approach for dealing with binary measurement systems due to its flexibility and ability to handle various conditions and restrictions.

Measurement Systems Analysis, Overview

Introduction

Measurement systems analysis (MSA) is a collection of statistical techniques designed to quantify the variability in a manufacturing process that is attributable to the metrology of that process. No process variability can be measured directly; that is, no process variability can be quantified without including the variability induced by measuring that process. MSA is therefore a study, separate from the processing of the product, that estimates the variability of the measurement process under conditions similar to those of the manufacturing process.

MSA is also called, variously, *measurement capability analysis* (in the context of determining whether or not a measurement system's variability is small enough compared with total process variability to adequately measure the process), *gauge studies*, or *gauge repeatability and reproducibility (GR&R) studies*.

Historical Perspective

Some of the earliest references to MSA in the statistical literature are found in the 1930s and 1940s. However, measurement precision was of concern even in older times. Shewhart [1] refers readers to a book by Goodwin [2] that was based on lecture notes from a course at MIT in the late 1800s. In 1948, Grubbs [3] laid out the first equations for estimating variability due to measurement repeatability.

The rise of MSA as a fundamental component of a process characterization study seems to have occurred in the 1980s, along with the rise of **statistical process control (SPC)** and other statistical quality methods in American manufacturing. Both the automotive and semiconductor industries mandate the use of gauge studies in quality improvement projects. Gauge studies are an integral part of both the Deming "Plan, Do, Check, Act" cycle, and the Six Sigma "Define, Measure, Analyze, Improve, Control" procedure. Wheeler and Lyday [4] include details on running gauge studies. In the early 1990s, SEMATECH included metrology system characterization as a

step in their equipment qualification plan [5]. A good review of methods for MSA can be found in Burdick *et al.* [6].

The design of the gauge study experiment has changed over the years. Early on, use of the standard 10-part, three-operator experimental design was extremely popular. In this design, multiple repeated measurements are performed by each operator, and the study yields estimates of variability due to repeats as well as variability due to operators. Another type of design used was the so-called 30 – 30 study, in which two studies are performed, the first with one setup and 30 repeated measurements, the other with 30 setups of one measurement each. The variance of the 30 repeated measurements is an estimate of repeatability, and the variance of the 30 setups is an estimate of reproducibility.

Terminology and methods of MSA have been somewhat standardized over the years; however, they have not been truly standardized. Care must be taken when performing or discussing MSA studies. Terms such as *repeatability* and *reproducibility* have been replaced by *variability due to repeats* or *variability due to operators*, for example. Industrial standard bodies have produced guideline documents that attempt standardization. See [7] for the automotive industry's guide to MSA or SEMI E89 [8] for the semiconductor industry's standard.

Experimental Design

A measurement process consists of the measurement tools themselves, including all hardware and software, as well as the procedures for using the tools: operators, setup and handling procedures, any off-line calculations or data entry, and **calibration** or other **preventive maintenance** frequency and technique.

A good measurement study will address the following questions: How big is the measurement error? What are the sources of the measurement error? Is the tool stable over time? Is the tool capable of making measurements for this process? What needs to be done to improve the measurement process?

Designing a MSA study is similar to designing any experiment (*see Gauge Repeatability and Reproducibility (R&R) Studies*). Up-front planning should include listing specific goals, obtaining measurement standards to use in the study, reviewing previous studies, identifying potential sources of variability,

estimating time and costs, assigning responsibilities, and securing management buy-in. Some of the potential sources of variability will not be studied, for example, yearly preventive maintenance activities. Others will be included in the study, for example, operator training and techniques or issues related to loading parts into the measurement tool. The factors that are not directly under study should still be documented and possibly added to a corrective action plan in the future.

Most gauge study information assumes the measurement tool gives continuous data and the true value of the standard remains constant over time (*see Gauge Repeatability and Reproducibility (R&R) Studies, Destructive Testing*).

The first step is to determine if the measurement tool is calibrated in the ranges of interest (*see Calibration*).

The fundamental equation of process variability is $\sigma_{\text{process}}^2 = \sigma_{\text{product}}^2 + \sigma_{\text{measurement}}^2$. That is, the variability seen in a process is made up of both variability due to the manufacturing process as well as variability due to the measurement process. Most gauge studies are designed to yield an estimate of $\sigma_{\text{measurement}}^2$. Given a list of possible contributors to $\sigma_{\text{measurement}}^2$, designing an experiment to estimate the size of the contributors to the total variability is usually straightforward. For example, consider an ellipsometer, used to measure the thickness of films on silicon wafers. Possible significant sources of variability include day-to-day effects, wafer-handling effects, and the actual measurement itself. The latter factor is often called *repeatability*. A good experiment will, therefore, include multiple days, multiple loads per day, and multiple repeated measurements per load. Note the hierarchical nature of the experimental factors. If the tool is not automated, multiple operators, or at least multiple levels of operator training, might be considered. If significant effects due to changes in ambient temperature and humidity over the day are expected, then measurements might be taken over multiple labor shifts.

Analytical Methods

Most of these effects will be treated as random factors in the ensuing model. Operators are often treated as fixed, especially if the operators in the study are the only operators used in the process or if different

operators represent different (fixed) levels of competency or training. Otherwise, Operator is treated as a random effect, and a variance component due to operators is calculated (*see Gauge Repeatability and Reproducibility (R&R), Variance Components in; Gauge Repeatability and Reproducibility (R&R) Studies, Confidence Intervals for*).

Once the estimate of measurement variability has been calculated, it can be used to answer the question of whether or not the measurement tool is capable of measuring the process under study. One popular metric for determining gauge capability is the precision-to-tolerance ratio, P/T. P/T is defined as the ratio of the measurement distribution to the process specification window, that is $6 \times \sigma_{\text{measurement}} / (USL - LSL)$. In automotive applications, the P/T ratio is often calculated as $5.15 \times \sigma_{\text{measurement}} / (USL - LSL)$. A rule of thumb is that a gauge with $P/T < 10\%$ is considered capable, one with $10\% < P/T < 30\%$ might be suitable, and one with $P/T > 30\%$ is not suitable for manufacturing. A large P/T ratio increases the misclassification probabilities (*see Gauge Repeatability and Reproducibility (R&R) Studies, Misclassification Rates*).

When specification limits are poorly defined, a **signal-to-noise** ratio (SNR) can be calculated. The SNR most often used is $SNR = \sigma_{\text{product}} / \sigma_{\text{measurement}}$. An SNR of at least 10 means that the measurement system is adequate for the process. A control system with a small SNR will have reduced sensitivity, meaning a longer time until an out-of-control condition is detected (*see Average Run Lengths and Operating Characteristic Curves*).

In addition to the metrology portion of the gauge study, care must be taken when choosing parts to use in the study. As with any statistical study, the results are applicable only to the population from which the sample was drawn. Therefore, it is crucial that the parts used in the study are representative of the process the measurement tool will be used for. Burdick *et al.* recommend using more parts and fewer measurements, as a rule.

Graphical Methods

In addition to the graphs generated for any other modeling effort, such as a time plot of the response, or a scatterplot of the response *versus* the factors, a key graph used in the analysis of gauge study data

Figure 1 Multi-vari chart of film thickness gauge study data

is the multi-vari plot, also called a *variability graph*. This graph plots the response on the vertical axis, with all hierarchical factors but the lowest on the horizontal axis. Figure 1 illustrates the concept. The data are simulated from a gauge study on a metrology tool measuring wafer film thickness. The study was conducted over 5 days, with three loads (setups) per day and three repeated measurements per load. One part was used in this example.

From the graph, it is easily seen that day-to-day and repeat-to-repeat variability are large, while load-to-load variability is small. The **variance components** and percent contribution of each to the total are found in Table 1.

Stability

It is important for a measurement system to remain stable, as a shift in the measurement distribution can lead to false out-of-control signals or false in-control behavior on the process **control chart**.

Stability of the measurement system is determined in a similar way to stability of a process. Data are

Table 1 Variance components for the film thickness gauge study

Source	Variance component	Percent of total (%)
Day	13.95	43
Load	1.98	6
Repeat	16.26	51
Total	32.19	100

collected over time, oversampling from the potential significant sources of variability, and control charts are calculated (*see Control Charts, Overview*).

Typically, a pool of standards is used for control charting a measurement system. Control limits are calculated using the entire pool, and then one standard is measured at specified intervals for the control system. When that standard breaks or is otherwise retired, the control limits need only to be shifted to match the mean value of the new standard from the pool. The width of the limits remains the same.

As with any SPC system, an out-of-control action plan should be developed. Often the original brainstorming session that determined the factors to be considered in the gauge study will provide information for the out-of-control action plan. For example, if yearly preventive maintenance activities have the potential to cause measurement system variability, but are not included in the gauge study, one line in the action plan flow chart might read: "Has the tool been returned properly from preventive maintenance activities?"

Summary

MSA is an important set of techniques used to determine if the measurement process is suitable for a manufacturing process. MSA gives an estimate of the measurement process variability and goodness metrics can then be calculated. Verification of the suitability of a measurement process should be the first step in any process improvement activity.

Gauge Repeatability and Reproducibility (R&R), Variance Components in

Introduction

Traditionally, a standard gauge repeatability and reproducibility (R&R) study consisted of a two-factor crossed design with operators and parts; with each operator measuring each part say r times (*see Gauge Repeatability and Reproducibility (R&R) Studies; Gauge Repeatability and Reproducibility (R&R) Studies, Misclassification Rates; Gauge Repeatability and Reproducibility (R&R) Studies, Confidence Intervals for; Measurement Systems Analysis, Capability Measures for; and [1]*). There are numerous situations where there are more than two factors, the design factors are not crossed but possibly nested, or the design involves crossed and nested factors. In this article, **variance components** for **gauge R&R** studies are presented for these more complex experimental situations.

Basic Notation and Assumptions

Consider the model

$$Y = X + E \quad (1)$$

where Y is the measured value of a randomly selected part, X is the true measurement of the part, and E is the measurement error. It is assumed that X and E are independent where $X \sim N(\mu_p, \sigma_p^2)$ and $E \sim N(\mu_M, \sigma_E^2)$. As a result, Y is normally distributed with mean $\mu_Y = \mu_p + \mu_M$ and variance $\sigma_Y^2 = \sigma_p^2 + \sigma_E^2$. The mean, μ_M , is considered measurement bias and often assumed to be zero since it is believed that the measurement instrument has been properly calibrated. In this article, let γ_p represent the variance of a process, γ_M represent the variance of the **measurement system**. The variance components for a typical gauge R&R study are described in Table 1.

In the next sections, three more complex designs are investigated for gauge R&R studies. Although variance component estimation can be completed for random, fixed, or mixed models, the focus in this article is on random-effect models. For more details on gauge R&R studies, variance components for

Table 1 Variance components notation

Parameter	Description
γ_p	Variance of the process (often referred to as part-to-part variability)
γ_M	Variance of the measurement system (repeatability and reproducibility)
$\sigma_T^2 = \gamma_p + \gamma_M$	Total variance of the response

mixed or fixed-effects models for various situations, and **confidence interval** construction see references [2–23].

Three-Factor Crossed Design

Suppose that there are three factors of interest in a particular gauge R&R study. Two of these factors may be operators (O) and parts (P) as in the two-factor crossed design, but a third random factor, V (such as time, test instrument, etc.), may also be present. Furthermore, assume there are o operators, p parts, v levels of the third factor, and r replicates. A model that can represent this three-factor random crossed design is

$$\begin{aligned}
 Y_{ijkl} = & \mu_Y + P_i + O_j + V_k + (PO)_{ij} + (PV)_{ik} \\
 & + (OV)_{jk} + (POV)_{ijk} + E_{ijkl} \\
 i = & 1, \dots, p; \quad j = 1, \dots, o; \\
 k = & 1, \dots, v; \quad l = 1, \dots, r
 \end{aligned} \quad (2)$$

where μ_Y is a constant, and $P_i, O_j, V_k, (PO)_{ij}, (PV)_{ik}, (OV)_{jk}, (POV)_{ijk}$, and E_{ijkl} are jointly independent normal random variables with means of zero and variances $\sigma_p^2, \sigma_O^2, \sigma_V^2, \sigma_{PO}^2, \sigma_{PV}^2, \sigma_{OV}^2, \sigma_{POV}^2$, and σ_E^2 , respectively. Table 2 displays the analysis of variance (ANOVA) (*see Analysis of Variance; Degrees of Freedom*) including the expected mean squares (*see Mean Square Error; Sum of Squares*) for this model.

Part variation in this case is the variation of the manufacturing process. Variability due to operators (O), the third factor V (assumed not to be part variation), and all interactions involving operators, parts, and V make up variation due to the measurement system. Using the notation in Table 1, we have $\gamma_p = \sigma_p^2$ and $\gamma_M = \sigma_O^2 + \sigma_V^2 + \sigma_{PO}^2 + \sigma_{PV}^2 + \sigma_{OV}^2 + \sigma_{POV}^2 + \sigma_E^2$. These parameters can be written in terms of their expected mean squares and estimated by equating

2 Gauge R&R, Variance Components in

Table 2 Analysis of variance and expected mean squares for a three-factor crossed model

Source of variation	Degrees of freedom	Mean square	Expected mean square
Parts (P)	$p - 1$	S_1^2	$\theta_1 = \sigma_E^2 + r\sigma_{POV}^2 + vr\sigma_{PO}^2 + or\sigma_{PV}^2 + ovrr\sigma_P^2$
Operators (O)	$O - 1$	S_2^2	$\theta_2 = \sigma_E^2 + r\sigma_{POV}^2 + vr\sigma_{PO}^2 + pr\sigma_{OV}^2 + pvr\sigma_O^2$
V	$V - 1$	S_3^2	$\theta_3 = \sigma_E^2 + r\sigma_{POV}^2 + or\sigma_{PV}^2 + pr\sigma_{OV}^2 + opr\sigma_V^2$
PO	$(p - 1)(o - 1)$	S_4^2	$\theta_4 = \sigma_E^2 + r\sigma_{POV}^2 + vr\sigma_{PO}^2$
PV	$(p - 1)(v - 1)$	S_5^2	$\theta_5 = \sigma_E^2 + r\sigma_{POV}^2 + or\sigma_{PV}^2$
OV	$(o - 1)(v - 1)$	S_6^2	$\theta_6 = \sigma_E^2 + r\sigma_{POV}^2 + pr\sigma_{OV}^2$
POV	$(p - 1)(o - 1)(v - 1)$	S_7^2	$\theta_7 = \sigma_E^2 + r\sigma_{POV}^2$
Replicates	$pov(r - 1)$	S_8^2	$\theta_8 = \sigma_E^2$

the associated mean squares to the expected mean squares. For γ_P , we have

$$\gamma_P = \sigma_P^2 = \frac{\theta_1 + \theta_7 - \theta_4 - \theta_5}{ovr} \quad (3)$$

and

$$\hat{\gamma}_P = \hat{\sigma}_P^2 = \frac{S_1^2 + S_7^2 - S_4^2 - S_5^2}{ovr} \quad (4)$$

For measurement system variation, we have

$$\gamma_M = \frac{\sum_{q=2}^8 c_q \theta_q}{povr} \quad (5)$$

and

$$\hat{\gamma}_M = \frac{\sum_{q=2}^8 c_q S_q^2}{povr} \quad (6)$$

where $c_2 = o$, $c_3 = v$, $c_4 = (p - 1)o$, $c_5 = (p - 1)v$, $c_6 = ov - o - v$, $c_7 = o + v - po - pv - ov + pov$, and $c_8 = pov(r - 1)$. It can be shown that because the design is balanced, $n_q S_q^2 / \theta_q \sim \chi_{n_q}^2$ where n_q represents **degrees of freedom** and $q = 2, \dots, 8$. The mean squares are also jointly independent. Because of both these properties, an ANOVA is appropriate.

The estimates of the variance components for the gauge R&R study can be used to estimate other capability measures such as signal-to-noise ratio (SNR) and C_p (see **Gauge Repeatability and Reproducibility (R&R) Studies, Misclassification Rates; Gauge Repeatability and Reproducibility (R&R) Studies, Confidence Intervals for; Measurement Systems Analysis, Capability Measures for**). The

authors in [3] provide details for constructing confidence intervals on variance components for the gauge R&R study with three-factor crossed designs.

Example

Burdick *et al.* [3] present the results of a gauge R&R study conducted on the fabrication of magnetic tape for computerized data storage (this example data was originally presented in [2]). In this study, there are $o = 3$ operators (automated test stations) evaluating the quality of $p = 9$ parts (tape heads). To measure characteristics of the heads, $v = 3$ tapes are used in each test station. All the heads are measured with each of the test station by tape combinations and $r = 2$ replicates for each treatment condition. The resulting design is a three-factor crossed design with the random-effects model given in equation (2). In the process of writing information to magnetic tape, *voltage* is measured at two different frequencies. *Resolution* is a ratio of the two voltages and is used as the response variable of interest (expressed as a percentage). Ideally, this ratio should be 100%. The specification limits are $LSL = 90\%$ and $USL = 110\%$. An ANOVA is carried out using a three-factor random-effects model with the resulting ANOVA table for this experiment given in Table 3.

Part variation of the manufacturing system is then

$$\begin{aligned} \hat{\gamma}_P &= \hat{\sigma}_P^2 = \frac{S_1^2 + S_7^2 - S_4^2 - S_5^2}{ovr} \\ &= \frac{102.8 + 0.418 - 1.074 - 1.884}{18} = 5.57 \end{aligned}$$

The variability due to the measurement system is more complicated but can also be estimated. For this

Table 3 ANOVA Table for three-factor crossed design

Source of variation	Degrees of freedom	Mean square
Parts (P)	8	102.800
Operators (O)	2	13.080
V	2	29.230
PO	16	1.074
PV	16	1.884
OV	4	2.932
POV	32	0.418
Replicates	81	0.139

problem $o = 3, v = 3, p = 9, r = 2$ resulting in $c_2 = o = 3, c_3 = v = 3, c_4 = (p - 1)o = 24, c_5 = (p - 1)v = 24, c_6 = ov - o - v = 3, c_7 = o + v - po - pv - ov + pov = 24$, and $c_8 = pov(r - 1) = 81$. The estimate is then

$$\begin{aligned}\hat{\gamma}_M &= \frac{\sum_{q=2}^8 c_q S_q^2}{povr} \\ &= \frac{3(13.08) + 3(29.23) + 24(1.074) + 24(1.884) + 3(2.932) + 24(0.418) + 81(0.139)}{9(3)(3)(2)} \\ &= 1.4\end{aligned}$$

Fortunately, the values for the measurement system variability and part variation can be found from standard statistical software such as Minitab. The variance components for each source are given in Table 4. We can further recognize that R&R can be estimated separately since $\gamma_M = \sigma_{\text{repeatability}}^2 + \sigma_{\text{reproducibility}}^2$. Repeatability would be $\hat{\sigma}_{\text{repeatability}}^2 = \hat{\sigma}_E^2 = 0.1394$ and reproducibility would be the sum of variance components due to operators and different

Table 4 Variance component estimates for three-factor crossed designs

Source	Variance component
Part	5.5726
Operator	0.1758
Tape	0.4599
Part $\times$ Operator	0.1094
Part $\times$ Tape	0.2442
Operator $\times$ Tape	0.1397
Part $\times$ Operator $\times$ Tape	0.1395
Error	0.1394

setups involving tape heads:

$$\begin{aligned}\hat{\sigma}_{\text{reproducibility}}^2 &= \hat{\sigma}_O^2 + \hat{\sigma}_V^2 + \hat{\sigma}_{PO}^2 + \hat{\sigma}_{PV}^2 + \hat{\sigma}_{OV}^2 + \hat{\sigma}_{POV}^2 \\ &= 0.1758 + 0.4599 + 0.1094 + 0.2442 \\ &\quad + 0.1397 + 0.1395 = 1.269\end{aligned}\quad (7)$$

Finally, there is variability in the estimates themselves and providing simple point estimates as done here is not enough. It would be more beneficial to provide *confidence intervals* on different parameters of interest. Burdick *et al.* [3] use generalized inference (*see Gauge Repeatability and Reproducibility (R&R) Studies, Misclassification Rates; Gauge Repeatability and Reproducibility (R&R) Studies, Confidence Intervals for*) to construct confidence intervals on γ_P and γ_M . They show that the 95% confidence interval on γ_P in this example is [2.46, 20.9] while the 95% confidence interval on γ_M is [1.00, 33.3]. As the authors discuss, the intervals given here are very wide due to the small number of operators ($o = 3$) and number of tapes ($v = 3$) in the study. They recommend having at least four degrees of freedom for the ANOVA random model to reduce the length of the intervals.

Two-Factor Random Nested Designs

Nested designs occur regularly in practice. Jensen [14] presents an example of a wafer process in semiconductor manufacturing. Measurements are taken at multiple locations on a wafer and wafers are processed in groups (lots). The goal of the measurement system is to account for variability among lots, among wafers, and within each wafer. Lots and wafers are selected at random from the process and are therefore random factors. In this process, it is assumed that wafers (W) are nested within lots (L) and replicates are nested within wafers. The quality characteristic of interest is the response and can be modeled using a two-factor random nested model (see [3] and [14]):

$$y_{ijk} = \mu_y + L_i + W_{j(i)} + E_{ijk} \quad (8)$$

where y_{ijk} is the k th measurement on the j th wafer within the i th lot, μ_y is the overall process mean, L_i represents the effect of the i th lot, and $W_{j(i)}$ represents the j th wafer nested within lot. $L_i, W_{j(i)}$, and E_{ijk} are jointly independent random variables with means zero and variances σ_L^2, σ_W^2 , and σ_e^2 ,

4 Gauge R&R, Variance Components in

Table 5 Analysis of variance and expected mean squares for a two-factor random nested model

Source of variation	Degrees of freedom	Mean square	Expected mean square
Lots	$l - 1$	S_1^2	$\theta_1 = \sigma_E^2 + r\sigma_W^2 + wr\sigma_L^2$
Wafers within lots	$l(w - 1)$	S_2^2	$\theta_2 = \sigma_E^2 + r\sigma_W^2$
Replicates	$lw(r - 1)$	S_3^2	$\theta_3 = \sigma_E^2$

respectively. The ANOVA for the model given in equation (8) is given in Table 5. Again, it can be shown that $n_q S_q^2 / \theta_q \sim \chi_{n_q}^2$ with n_q degrees of freedom for the various components. The manufacturing process variability, γ_P , is due to lots and wafers while measurement system variability, γ_M , is due to replication error only. It can be shown that

$$\gamma_P = \frac{\theta_1 + (w - 1)\theta_2 - w\theta_3}{wr} \quad (9)$$

and

$$\gamma_M = \theta_3 \quad (10)$$

The estimates are then

$$\hat{\gamma}_P = \frac{S_1^2 + (w - 1)S_2^2 - wS_3^2}{wr} \quad (11)$$

and

$$\hat{\gamma}_M = S_3^2 \quad (12)$$

For this problem, there were $w = 2$ wafers selected from $l = 20$ lots, and $r = 9$ replicates. The resulting ANOVA is given in Table 6. The point estimates for γ_P and γ_M are then

$$\begin{aligned} \hat{\gamma}_P &= \frac{S_1^2 + (w - 1)S_2^2 - wS_3^2}{wr} \\ &= \frac{739.50 + 97.98 - 2(19.03)}{2(9)} = 44.41 \end{aligned}$$

Table 6 ANOVA table for two-factor nested design

Source of variation	Degrees of freedom	Mean square
Lots	19	739.50
Wafers within lots	20	97.98
Replicates	320	19.03

and

$$\hat{\gamma}_M = S_3^2 = 19.03$$

Again, point estimates do not give the practitioner the whole picture with respect to the amount of variability in the system. It would be more beneficial to examine confidence intervals on γ_P and γ_M . Burdick *et al.* [3] provide several approaches for constructing confidence intervals for this two-factor nested design. Also see [24] and [25].

Designs with Both Crossed and Nested Factors

There are experimental situations where the model involves both crossed and nested factors. The variance components for this particular model will be illustrated using an example from [6] and further detailed in [3]. The example involves three factors in a semiconductor manufacturing process. Measurements are recorded at four sites (S) on a wafer during the manufacturing process. The data are collected over three shifts (operators (O)) each day (D) for a seven-day period. Since operators may differ by day, the factor operator is treated as nested within day. The model of interest for this problem is

$$\begin{aligned} Y_{ijkl} &= \mu_Y + D_i + O_{j(i)} + S_k + (OS)_{jk(i)} + E_{ijkl} \\ \text{for } i &= 1, \dots, d; \quad j = 1, \dots, o; \quad k = 1, \dots, s; \\ \text{and } l &= 1, \dots, r \end{aligned} \quad (13)$$

μ_Y is a constant, $D_i \sim N(0, \sigma_D^2)$, $O_{j(i)} \sim N(0, \sigma_{O(D)}^2)$, $S_k \sim N(0, \sigma^2)$, $(OS)_{jk(i)} \sim N(0, \sigma_{SO(D)}^2)$, and $E_{ijkl} \sim N(0, \sigma_E^2)$. Furthermore, D_i , $O_{j(i)}$, S_k , $(OS)_{jk(i)}$, and E_{ijkl} are jointly independent. Day is treated as a blocking variable (see **Blocking**) and as a result, there is no day-by-site interaction in the model. The ANOVA and expected mean squares are given in Table 7 where $d = 7$, $s = 4$, $o = 3$, and $r = 4$.

In this problem, the process variation is a function of the variability due to day and site. In particular, $\gamma_P = \sigma_D^2 + \sigma_S^2$. The variation due to the measurement system is $\gamma_P = \sigma_{O(D)}^2 + \sigma_{SO(D)}^2 + \sigma_E^2$. It can be shown that

$$\gamma_P = \frac{d(\theta_1 - \theta_2) + s(\theta_3 - \theta_4)}{dosr} \quad (14)$$

and

$$\gamma_M = \frac{\theta_2 + (s - 1)\theta_4 + s(r - 1)\theta_5}{sr} \quad (15)$$

Table 7 Analysis of variance and expected mean squares for a model with crossed and nested factors

Source of variation	Degrees of freedom	Mean square	Expected mean square
Days	$d - 1$	S_1^2	$\theta_1 = \sigma_E^2 + r\sigma_{SO(D)}^2 + sr\sigma_{O(D)}^2 + osr\sigma_D^2$
Operators within days $O(D)$	$d(o - 1)$	S_2^2	$\theta_2 = \sigma_E^2 + r\sigma_{SO(D)}^2 + sr\sigma_{O(D)}^2$
Sites (S)	$s - 1$	S_3^2	$\theta_3 = \sigma_E^2 + r\sigma_{SO(D)}^2 + dor\sigma_S^2$
$S \times O(D)$	$(s - 1)(od - 1)$	S_4^2	$\theta_4 = \sigma_E^2 + r\sigma_{SO(D)}^2$
Replicates	$dos(r - 1)$	S_5^2	$\theta_5 = \sigma_E^2$

The point estimates are then

$$\hat{\gamma}_P = \frac{d(S_1^2 - S_2^2) + s(S_3^2 - S_4^2)}{dosr} \quad (16)$$

and

$$\hat{\gamma}_M = \frac{S_2^2 + (s - 1)S_4^2 + s(r - 1)S_5^2}{sr} \quad (17)$$

The resulting ANOVA table for the semiconductor problem is given in Table 8.

The point estimates for the process variation and measurement system variation for the semiconductor example are

$$\begin{aligned} \hat{\gamma}_P &= \frac{d(S_1^2 - S_2^2) + s(S_3^2 - S_4^2)}{dosr} \\ &= \frac{7(6.480 - 1.404) + 4(35.220 - 1.447)}{7(3)(4)(4)} \\ &= 0.508 \end{aligned}$$

and

$$\begin{aligned} \hat{\gamma}_M &= \frac{S_2^2 + (s - 1)S_4^2 + s(r - 1)S_5^2}{sr} \\ &= \frac{1.404 + 3(1.447) + 4(3)(0.529)}{4(4)} \\ &= 0.756 \end{aligned}$$

Table 8 ANOVA table for design involving crossed and nested factors

Source of variation	Degrees of freedom	Mean square
Days	6	6.480
Operators within days $O(D)$	14	1.404
Sites (S)	3	35.220
$S \times O(D)$	60	1.447
Replicates	252	0.529

Table 9 Variance component estimates for the semiconductor example

Source of variation	Variance component
Days	0.10570
Operators within days $O(D)$	-0.00272
Sites (S)	0.40200
$S \times O(D)$	0.22950
Replicates	0.52920

As in the previous examples, it is recommended to construct confidence intervals on these variances. The individual variance component estimates are given in Table 9. It should be noted that there may be some slight differences in the estimates found using different software packages or doing the calculations by hand due to rounding. The values given in Table 9 illustrate one of the problems that can result from the estimation procedure used for computation of the variance components. Notice that the variance component estimate for operators within days is negative. When this occurs, one recommendation has been to set this component equal to zero. Although the full ANOVA table is not reported here, when the test was conducted, the nested factor, operators within days, was statistically insignificant at the 0.05 level of significance. The authors in [3] removed this factor from the model, analyzed the results for the reduced model, and then calculated the variance components and resulting process and measurement system variation.

Conclusions

Variance component estimation for three complex experimental designs has been presented where variance estimates, such as process variation and measurement system variation, have been shown to be linear combinations of the appropriate individual

variance components. The variance components were estimated by equating the expected mean squares for the factor (or interaction) of interest to its observed mean square value. It is recommended that the practitioner should not rely simply on point estimates of the variance components, but also consider confidence intervals on the variance components. Confidence intervals provide a measure of precision associated with the estimated variance component and can give the practitioner insight as to whether more operators should be included in a future study or perhaps more parts are needed.

In addition, all the examples presented here assumed that every factor was random and the design balanced. There are many scenarios where some of the factors involved in the study are fixed so that the resulting model is mixed (contains both random and fixed factors). It is also possible that the resulting design will not be balanced. Several studies have been conducted on variance component estimation for this situation. For more detailed information on these designs and construction of confidence intervals see [12, 24–29].

Gauge Repeatability and Reproducibility (R&R) Studies, Misclassification Rates

Introduction

In order to properly monitor and improve a manufacturing process, it is necessary to measure attributes of the process output. For any group of measurements collected for this purpose, at least part of the variation is due to the measurement system. This is because repeated measurements of any particular item do not always result in the same value. In order to ensure that measurement system variability is not harmfully large, it is necessary to conduct a gauge repeatability and reproducibility (R&R) study (*see Gauge Repeatability and Reproducibility (R&R) Studies; Measurement Systems Analysis, Overview*). For readers who are unfamiliar with these terms, a gauge is any device used to obtain measurements on the output of the manufacturing process. In a **gauge R&R** study, replicate measurements are collected on units using several different operators, setups, or time periods. Two components of variability are generated in such studies: repeatability and reproducibility. Repeatability represents the gauge variability when it is used to measure the same unit (with the same operator or setup or in the same time period). Reproducibility refers to the variability arising from different operators, setups, or time periods. By comparing the relative magnitudes of these sources of variation with the variation inherent in the manufacturing process, decisions are made concerning the capability of the measurement system. In particular, if variation due to the measurement system is small relative to variation of the process, then the measurement system is deemed capable and used to monitor the process.

Originally, gauge R&R studies were conducted using a tabular method based on ranges and **control charts**. Today, however, gauge R&R studies are analyzed using analysis of variance (ANOVA) models (*see Analysis of Variance; Gauge Repeatability and Reproducibility (R&R), Variance Components in*). This is because the ANOVA models provide greater flexibility in modeling the data and constructing measures of uncertainty.

The Measurement Model

The measurement model used in a gauge R&R study can be written as

$$Y = X + E \quad (1)$$

where Y is the measured value of a randomly selected part from a manufacturing process, X is the true value of the part, and E is the measurement error contributed by the measurement system. The terms X and E are independent normal random variables with means μ_P and μ_M , and variances γ_P and γ_M , respectively. The subscripts P and M denote process and measurement system, respectively. These assumptions imply that Y has a **normal distribution** with mean $\mu_Y = \mu_P + \mu_M$ and variance $\gamma_Y = \gamma_P + \gamma_M$. Additionally, the **covariance** between Y and X is γ_P . The mean μ_M is referred to as the *bias* of the measurement system. This bias can typically be eliminated by proper **calibration** of the system, and so it is often assumed that $\mu_Y = \mu_P$.

Parameters of Interest

Table 1 reports parameters in model (1) that are the focus of most gauge R&R studies.

It is useful to describe these parameters in the context of an example. Houf and Berman [1] describe a process used to manufacture a power module for a line of motor starters. An important attribute is the thermal performance of the power module. Measurements of thermal performance are taken on a sample of power modules using a thermal resistance measuring instrument. The units of measurement are degree celsius per watt. Variability in the data can be attributed to

1. the manufacturing process used to produce the power modules (γ_P) and
2. measurement error contributed by the thermal resistance measuring instrument (γ_M).

The purpose of the gauge R&R study is to determine if the variability due to 2 is small relative that due to 1. There are two criteria commonly used for this purpose. Both are based on the parameters shown in Table 1.

The precision-to-tolerance ratio (PTR) is

$$PTR = \frac{k\sqrt{\gamma_M}}{USL - LSL} \quad (2)$$

2 Gauge R&R Studies, Misclassification Rates

Table 1 Parameters in a gauge R&R study

Symbol	Definition
μ_Y	Mean of population of measurements
γ_P	Variance of the process
γ_M	Variance of the measurement system
$\gamma_R = \frac{\gamma_P}{\gamma_M}$	Ratio of process variance to measurement variance

where USL and LSL are the upper and lower specification limits, respectively, and k is either 5.15 or 6. The Automotive Industry Action Group (AIAG) *Measurement Systems Analysis* manual [2, p. 77] recommends the following rule of thumb for using PTR to determine the capability of a measurement system:

1. $PTR \leq 0.1$: the measurement system is capable.
2. $0.1 < PTR \leq 0.3$: the measurement system may be capable depending on factors such as process capability and costs of misclassification.
3. $PTR > 0.3$: the measurement system is not capable.

The signal-to-noise ratio (SNR) is a function of γ_R defined as

$$SNR = \sqrt{2\gamma_R} \quad (3)$$

The AIAG *Measurement Systems Analysis* manual [2, p. 117] defines SNR as the number of distinct categories that can be reliably distinguished by the measurement system. A value of five or greater is recommended, and a value less than two indicates the measurement system is of no value in monitoring the process.

The PTR and SNR are popular criteria for evaluating the capability of a measurement system. Burdick *et al.* [3] critique these criteria and review other criteria reported in the literature. However, given that a measurement system is designed to discriminate between good and bad products, a more meaningful criterion might be the probability of part misclassification. We now describe how this criterion can be used to determine the capability of a measurement system.

Definition of Misclassification Rates

The joint **probability density function** of Y and X is bivariate normal with mean vector $[\mu_Y \mu_P]^T$ and

covariance matrix

$$\begin{bmatrix} \gamma_P + \gamma_M & \gamma_P \\ \gamma_P & \gamma_P \end{bmatrix} \quad (4)$$

where $[\bullet]^T$ represents the transpose operator. We represent this density function as $f(y, x)$. A manufactured part is in conformance if

$$LSL \leq X \leq USL \quad (5)$$

A measurement system will pass a part if

$$LSL \leq Y \leq USL \quad (6)$$

If equation (5) is true and equation (6) is false, then a conforming part is misclassified as a failure. This is called a *false failure* (FF). Alternatively, if equation (5) is false but equation (6) is true, a failure is misclassified as a good part. This is called a *missed fault* (MF). Figure 1 illustrates the regions of FF and MF on an equal density contour of the bivariate normal distribution.

Probabilities of the misclassification errors FF and MF are computed as either joint or conditional probabilities. To demonstrate, an FF occurs when equation (5) is true and equation (6) is false. Representing this joint probability with the symbol δ ,

$$\begin{aligned} \delta &= \Pr[(LSL \leq X \leq USL) \text{ and} \\ &\quad (Y < LSL \text{ or } Y > USL)] \\ &= \Pr[(LSL \leq X \leq USL \text{ and } Y < LSL) \\ &\quad \text{or } (LSL \leq X \leq USL \text{ and} \\ &\quad Y > USL)] \end{aligned}$$

Figure 1 MF and FF regions of an equal density contour

$$\begin{aligned}
&= \int_{LSL}^{USL} \int_{-\infty}^{LSL} f(y, x) dy dx \\
&\quad + \int_{LSL}^{USL} \int_{USL}^{\infty} f(y, x) dy dx \quad (7)
\end{aligned}$$

An MF occurs when equation (5) is false and equation (6) is true. If we represent this joint probability with the symbol β ,

$$\begin{aligned}
\beta &= \Pr[(X < LSL \text{ or } X > USL) \text{ and} \\
&\quad (LSL \leq Y \leq USL)] \\
&= \Pr[(X < LSL \text{ and } LSL \leq Y \leq USL) \text{ or} \\
&\quad (X > USL \text{ and } LSL \leq Y \leq USL)] \\
&= \int_{-\infty}^{LSL} \int_{LSL}^{USL} f(y, x) dy dx \\
&\quad + \int_{USL}^{\infty} \int_{LSL}^{USL} f(y, x) dy dx \quad (8)
\end{aligned}$$

The probability δ is referred to as *producer's risk* and the probability β is referred to as *consumer's risk*. Some investigators prefer to compute the conditional probabilities

$$\delta_C = \frac{\delta}{\pi} \quad (9)$$

and

$$\beta_C = \frac{\beta}{1 - \pi} \quad (10)$$

where

$$\pi = \int_{LSL}^{USL} f(x) dx \quad (11)$$

is the probability of a good part and $f(x)$ is the marginal probability density function for X , which is normal with mean μ_P and variance γ_P . In words, δ_C is the conditional probability that a part fails given the part is good. The symbol β_C is the conditional probability that a part passes given the part is bad.

When considering whether misclassification rates are “sufficiently small”, it is useful to compare them to what one could obtain by chance. To demonstrate, suppose the value of π in equation (11) is known. A chance process for classifying parts is to take no measurements and randomly classify π of the parts as “good” and $1 - \pi$ as “bad”. For this chance process, the probability of an FF is

$$\delta^* = \Pr[(LSL \leq X \leq USL) \text{ and}$$

(Part classified as bad)]

$$\begin{aligned}
&= \Pr(LSL \leq X \leq USL) \times \Pr(\text{Part classified} \\
&\quad \text{as bad}) \\
&= \pi(1 - \pi) \quad (12)
\end{aligned}$$

Likewise, the probability of an MF for this chance process is

$$\begin{aligned}
\beta^* &= \Pr[(X < LSL \text{ or } X > USL) \text{ and} \\
&\quad (\text{Part classified as good})] \\
&= \Pr(X < LSL \text{ or } X > USL) \times \Pr(\text{Part} \\
&\quad \text{classified as good}) \\
&= (1 - \pi)\pi \quad (13)
\end{aligned}$$

Thus, for a measurement system to be useful, the misclassification rates δ and β should be less than what one could get by chance, δ^* and β^* . One can make a similar argument using the conditional probabilities δ_C and β_C . In this case, the conditional probabilities that could be obtained by chance are $\delta_C^* = 1 - \pi$ and $\beta_C^* = \pi$.

To better interpret misclassification rates, it is useful to compute ratios of the misclassification rates to the chance rates. If a measurement system is able to discriminate better than the chance process, these indexes will be less than one. These ratios are defined as

$$\delta_{\text{index}} = \frac{\delta}{\delta^*} = \frac{\delta}{\pi(1 - \pi)} \quad (14)$$

and

$$\beta_{\text{index}} = \frac{\beta}{\beta^*} = \frac{\beta}{(1 - \pi)\pi} \quad (15)$$

Notice $\delta_C/\delta_C^* = \delta_{\text{index}}$ and $\beta_C/\beta_C^* = \beta_{\text{index}}$ so these indexes can be used for both the unconditional and conditional definitions of misclassification rates.

The misclassification indexes in equations (14) and (15) can be computed for given values of μ_Y , μ_P , γ_P , γ_M , LSL, and USL by integrating bivariate normal distributions as shown in equations (7), (8), and (11). More typically, these parameters are unknown and must be estimated from the data obtained in the R&R study. If we assume $\mu_Y = \mu_P$, the overall sample mean provides an estimate of both μ_Y and μ_P . If there is a systematic bias in the system, then it is necessary to estimate μ_P from another source of information. Such an estimate might be based on historical data

4 Gauge R&R Studies, Misclassification Rates

from the process. Estimates for γ_P and γ_M will be available from the measurement data even if systematic bias is present in the measurement system.

One approach to account for the uncertainty in the estimates of μ_Y , μ_P , γ_P , and γ_M is to compute **confidence intervals** for δ_{index} and β_{index} , as well as for the misclassification rates in equations (7–10). A method to compute such intervals based on generalized inference is detailed in Burdick *et al.* [4]. Simply, the calculations are performed by replacing the parameters μ_Y , μ_P , γ_P , and γ_M with appropriate generalized pivotal quantities.

An Example

The two-factor crossed random effects ANOVA model with interaction is the classical gauge R&R design. Typically, the two factors are referred to as *parts* and *operators*. Table 2 presents the ANOVA table for an artificial data set based on the experiment described by Houf and Berman [1]. The response variable is the thermal performance of a module measured in degree celsius per watt. Each response has been multiplied by 100 for convenience of scale. The data represent measurements of 20 parts recorded by six operators. Each part is measured two times by each operator. It is assumed that parts and operators are selected at random from larger populations. The mean of all the observations is 36.9 and the specification limits are $LSL = 18$ and $USL = 58$.

The confidence intervals for the misclassification rates are shown in Table 3. These are computed using the process described in Burdick *et al.* [4].

Table 3 suggests the measurement system in this example is capable since both misclassification indexes are less than one. This suggests the misclassification rates are better than those obtained by chance, and that there is information contained in the measurements.

Table 2 ANOVA for example

Source of variation	Degrees of freedom	Mean square
Parts (modules)	19	591.5
Operators	5	13.59
$P \times O$	95	2.060
Replicates	120	0.7333

Table 3 95% confidence intervals for misclassification rates (bounds for δ , δ_C , β , and β_C are $\times 10^{-6}$)

Parameter	Lower bound	Upper bound
δ	199	8594
δ_C	199	9135
δ_{index}	0.141	0.854
β	63	6138
β_C	98 746	248 703
β_{index}	0.105	0.249

Summary

Although the two-factor random effects design is the most common gauge R&R design, more complex ANOVA designs are needed to properly model some measurement systems. Burdick *et al.* [5] provide methods for constructing confidence intervals on the misclassification rates in addition to the parameters shown in Table 1 for a wide variety of ANOVA designs (also see **Gauge Repeatability and Reproducibility (R&R) Studies, Confidence Intervals for**). Computer programs in Excel and SAS are available at the book's website.

Gauge Repeatability and Reproducibility (R&R) Studies, Confidence Intervals for

Introduction: Measurement Errors in Data

Gauge repeatability and reproducibility (R&R) studies are commonly conducted in industrial settings with the goal of determining if a gauge or, broadly, a **measurement system** is adequate for monitoring a manufacturing process. Such studies are also termed as *gauge capability studies*. Variables type measurement (Y) of a manufactured part can be thought of as comprising the true value (P) of the part plus measurement error (M). Measurement errors are attributable to the gauge (repeatability) or gauge operator/operating conditions (reproducibility). A given part is regarded as nonconforming if its true value lies outside of design specification (LSL, USL). Since the true value is never directly observable, the practical approach is to check whether Y lies within (LSL, USL). This approach assumes that measurement error M is small relative to the true value P . The common statistical model for analyzing measurement errors assumes additivity of effects and normal distributed variables: $Y = P + M$. The fundamental goal of **gauge R&R** studies is to determine if the measurement system variance (σ_M^2) is practically small relative to the manufacturing process variance (σ_P^2). We will discuss common gauge R&R measures and **confidence intervals** (CIs) for them.

Common Measures of Gauge Capability

The common measures of gauge capability in R&R studies are derived from two components of the measurement variance: $\sigma_Y^2 = \sigma_P^2 + \sigma_M^2$.

Measurement Error Variance

σ_M^2 is the variance of measurement errors. It is typically decomposed into repeatability variance and reproducibility variance. Repeatability variance is attributed to the variation among repeated measurements made by the same operator on the

same part using the same gauge. Reproducibility variance is attributed to the variation among repeated measurements made on the same part by different operators with the same gauge. Rescaling σ_M , we get a commonly used measure of gauge capability called the *precision-to-tolerance ratio* (PTR), $PTR = 6\sigma_M/(USL - LSL)$. Unfortunately, as discussed in Montgomery and Runger [1], low PTR could be due to a large tolerance ($USL - LSL$) rather than small σ_M . Consequently, we are not assured that measurement errors (E) are small relative to the true values (P).

Part Variance

The part variance is denoted by σ_P^2 . If the parts used in the R&R study are randomly selected from the production process, then this variance is also taken to be the variance of the production process. However, if the parts do not represent a random sample from the process but include unusual parts that exceed specification (as suggested in [1]), then this variance cannot be regarded as a measure of production process variance.

Comparing Part and Measurement Variance

The comparison between parts and measurement variance can be made using three measures. The most direct being the ratio, $\gamma = \sigma_P^2/\sigma_M^2$. γ is a direct comparison between parts variation and measurement error variation. Another is the intraclass correlation, $\rho = \sigma_P^2/(\sigma_P^2 + \sigma_M^2) = \gamma/(1 + \gamma)$. ρ is the fraction contributed by parts variation to the variance of measurements, $\sigma_Y^2 = \sigma_P^2 + \sigma_M^2$. Finally, there is the signal-to-noise ratio (SNR), $SNR = \sqrt{2\gamma}$, which the automotive industry action group (AIAG) Measurement System Analysis Manual [2] defines SNR as the number of distinct categories that can be reliably distinguished by the measurement system. As a rule of thumb, SNR greater than 5 suggests a capable measurement system while SNR less than 2 suggests an incapable measurement system. These three measures (γ , ρ , SNR) are mathematically equivalent and therefore estimates for ρ and SNR are easily derived from that for γ .

Misclassification Probabilities

Besides these three measures, the capability of a measurement system can also be appraised by its

2 Gauge R&R Studies, Confidence Intervals for

ability to correctly or incorrectly classify good and bad parts. This is true regardless of whether the measurement system gives variables (quantitative) or attribute (pass/fail) readings. Misclassification of a good part as bad (false failure) results in wastage of resources through scrapping or reworking of good parts (*see Gauge Repeatability and Reproducibility (R&R) Studies, Misclassification Rates; Measurement Systems Analysis, Capability Measures for*). Misclassification of a bad part as good (missed fault) results in customer dissatisfaction. Therefore, a capable measurement system should have small probabilities of misclassification, where the false failure probability is defined as $\delta = \Pr(\text{a good part is classified as bad})$ and the missed fault probability is defined as $\beta = \Pr(\text{a bad part is classified as good})$. These probabilities are respectively defined by integrating the joint density of Y and P over the appropriate regions A and B which define the false failure and missed fault, that is, $\delta = \iint_A f(y, p) dy dp$ and

$$\beta = \iint_B f(y, p) dy dp \text{ with}$$

$$A = \{(y, p) : y \notin (LSL, USL), p \in (LSL, USL)\}$$

and

$$B = \{(y, p) : y \in (LSL, USL), p \notin (LSL, USL)\}.$$

Classical Gauge R&R Study

Consider the classical gauge R&R design, also known as a *balanced two-factor crossed random model with interaction*. The typical set up consists of p randomly chosen parts independently measured r times

by each of o operators. The k th measurement of the i th part by the j th operator is denoted by $Y_{ijk} = \mu_Y + P_i + O_j + PO_{ij} + E_{ijk}$ where μ_Y is a constant, $P_i, O_j, PO_{ij}, E_{ijk}$ are jointly independent, normally distributed with means as zero and variances $\sigma_P^2, \sigma_O^2, \sigma_{PO}^2$, and σ_E^2 respectively. These variances are commonly referred to as **variance components**. In terms of R&R variances, σ_E^2 is repeatability variance, and $(\sigma_O^2 + \sigma_{PO}^2)$ is the reproducibility variance. Collectively, $(\sigma_O^2 + \sigma_{PO}^2 + \sigma_E^2)$ is the measurement error variance. Estimates and CIs for R&R measures are based entirely on the analysis of variance (ANOVA) approach. The ANOVA table for the classical gauge R&R model is shown in Table 1. The point estimates are derived by first expressing the variances as linear functions of the expected mean squares (EMS) in column 2 of Table 2 and replacing each θ by its mean squares (S^2) in column 3 of Table 2. Negative estimates for $\hat{\gamma}$ and $\hat{\sigma}_P^2$ are assigned as zero.

Confidence Intervals for R&R Measures

In the classical R&R study and other R&R study designs based on the ANOVA approach, the relevant R&R measures such as σ_M^2 and γ can be expressed as functions of variance components. These measures are increasingly being studied using CIs, which incorporate the statistical uncertainty associated with the **estimation** procedure. An exact $100(1 - \alpha)\%$ CI for a measure is a random interval (L, U) based on the measurements such that there is a $(1 - \alpha)$ probability that the measure lies within it. Typical values for $(1 - \alpha)$ are 0.90, 0.95, and 0.99. In the absence of exact CI, an approximate CI is considered. An approximate $100(1 - \alpha)\%$ CI has

Table 1 ANOVA table for classical gauge R&R model

Sources of variation	Degrees of freedom	Mean squares ^(a)	Expected mean squares (EMS)
Parts O	$p - 1$	S_P^2	$\theta_P = or\sigma_P^2 + r\sigma_{PO}^2 + \sigma_E^2$
Operators P	$o - 1$	S_O^2	$\theta_O = pr\sigma_P^2 + r\sigma_{PO}^2 + \sigma_E^2$
Interaction PO	$(p - 1)(o - 1)$	S_{PO}^2	$\theta_{PO} = r\sigma_{PO}^2 + \sigma_E^2$
Replicates	$po(r - 1)$	S_E^2	$\theta_E = \sigma_E^2$

^(a)Mean squares are defined using: $S_P^2 = or \sum_i (\bar{Y}_{i**} - \bar{Y}_{***})^2 / (p - 1)$, $S_O^2 = pr \sum_j (\bar{Y}_{*j*} - \bar{Y}_{***})^2 / (o - 1)$,

$$S_{PO}^2 = r \sum_i \sum_j (\bar{Y}_{ij*} - \bar{Y}_{i**} - \bar{Y}_{*j*} + \bar{Y}_{***})^2 / (p - 1)(o - 1), \quad S_E^2 = \sum_i \sum_j \sum_k (Y_{ijk} - \bar{Y}_{ij*})^2 / po(r - 1),$$

$$\bar{Y}_{***} = \sum_i \sum_j \sum_k Y_{ijk} / por, \quad \bar{Y}_{ij*} = \sum_k Y_{ijk} / r, \quad \bar{Y}_{i**} = \sum_j \sum_k Y_{ijk} / or, \quad \bar{Y}_{*j*} = \sum_i \sum_k Y_{ijk} / pr.$$

Table 2 Estimation of R&R measures

Measure	In terms of EMS	Estimate
$\sigma_{\text{repeatability}}^2 = \sigma_E^2$	θ_E	$\hat{\sigma}_{\text{repeatability}}^2 = S_E^2$
$\sigma_{\text{reproducibility}}^2 = \sigma_O^2 + \sigma_{PO}^2$	$(\theta_O + (p-1)\theta_{PO} - p\theta_E)/pr$	$\hat{\sigma}_{\text{reproducibility}}^2 = \max\{0, (S_O^2 + (p-1)S_{PO}^2 - pS_E^2)/pr\}$
$\sigma_M^2 = \sigma_O^2 + \sigma_{PO}^2 + \sigma_E^2$	$(\theta_O + (p-1)\theta_{PO} + p(r-1)\theta_E)/pr$	$\hat{\sigma}_M^2 = \frac{S_O^2 + (p-1)S_{PO}^2 + p(r-1)S_E^2}{pr}$
σ_P^2	$(\theta_P - \theta_{PO})/or$	$\hat{\sigma}_P^2 = \max\{0, (S_P^2 - S_{PO}^2)/or\}$
$\gamma = \sigma_P^2/\sigma_M^2$	$\frac{p\theta_P - p\theta_{PO}}{o\theta_O + (p-1)o\theta_{PO} + po(r-1)\theta_E}$	$\hat{\gamma} = \hat{\sigma}_P^2/\hat{\sigma}_M^2$

approximate $(1 - \alpha)$ probability that the measure lies within it. Except for the repeatability variance, which has exact χ^2 CI, the other R&R measures do not have exact CIs. Several approximate CI methods for variance components function have been recommended for R&R studies, including for instance, the Satterthwaite's [3–5], asymptotic intervals based on restricted maximum-likelihood (REML) estimates [5], modified large sample (MLS), and generalized confidence intervals (GCIs) [6, 7]. The Satterthwaite's and REML intervals have been shown to be sometimes inadequate in coverage probabilities [5, 8] in small and moderate samples. Currently, only the MLS and GCI approaches are recommended as they have been shown through extensive simulation studies to provide coverage probabilities that are close to the stated confidence level even in small samples. Comprehensive discussion of these intervals and other analysis/design aspects for gauge R&R studies are found in Burdick *et al.* [9, 10].

Modified Large Sample Intervals

The MLS method was first introduced by Graybill and Wang [11]. Burdick and Larsen [5] recommends this MLS method for an approximate $100(1 - \alpha)\%$ CI for measurement error variance σ_M^2 :

$$(\hat{\sigma}^2 - \sqrt{V_L}/pr, \hat{\sigma}_M^2 + \sqrt{V_U}/pr) \text{ where } V_L = G_2^2 S_O^4 + G_3^2 (p-1)^2 S_{PO}^4 + G_4^2 p^2 (r-1)^2 S_E^4, \\ V_U = H_2^2 S_O^4 + H_3^2 (p-1)^2 S_{PO}^4 + H_4^2 p^2 (r-1)^2 S_E^4, \\ G_q = 1 - F_{\alpha/2; \infty, n_q}, H_q = F_{1-\alpha/2; \infty, n_q} - 1,$$

$q = 2, 3, 4, n_2 = o - 1, n_3 = (p-1)(o-1), n_4 = po(r-1)$, and $F_{\alpha; d1, d2}$ is the 100α th percentile of the F distribution with $d1$ and $d2$ **degrees of freedom**. As suggested by the given CI expression, MLS CIs have explicit but complicated expressions. In special cases where certain variance components are zero or as the dimensions o or p increase to infinity, the MLS approximate intervals reduce to exact intervals. The advantage of MLS intervals is that they are easily implemented in computer spreadsheets and always produce unique numerical values. More recommendations and a comprehensive discussion of MLS intervals in R&R studies are found in [5, 9, 10]. A complete catalogue of MLS methods in general ANOVA models is found in Burdick and Graybill [12].

Generalized Confidence Intervals

The GCI method is a computer-intensive method first suggested by Weerahandi [13] and first applied to R&R studies in Hamada and Weerahandi [6]. It uses the generalized pivotal quantity (GPQ) which is distributed free of the parameters of interest. Chiang [7] developed a similar method using surrogate variables which are comparable to the GPQ. Approximate intervals are constructed with **percentiles** of GPQ, using either numerical integration or simulation.

The procedure is a simple one using **Monte Carlo simulation**:

1. Define the GPQ for the EMS (θ) in Table 1:
 $\tilde{\theta}_P = (p-1)s_P^2/\chi_{(p-1)}^2, \tilde{\theta}_O = (o-1)s_O^2/\chi_{(o-1)}^2,$
 $\tilde{\theta}_{PO} = (p-1)(o-1)s_{PO}^2/\chi_{(p-1)(o-1)}^2,$
 $\tilde{\theta}_E = po(r-1)s_E^2/\chi_{po(r-1)}^2,$

4 Gauge R&R Studies, Confidence Intervals for

Table 3 GPQ for R&R measure

Measure	GPQ
$\sigma_{\text{repeatability}}^2 = \sigma_E^2$	$\tilde{\sigma}_{\text{repeatability}}^2 = \tilde{\theta}_E$
$\sigma_{\text{reproducibility}}^2 = \sigma_O^2 + \sigma_{PO}^2$	$\tilde{\sigma}_{\text{reproducibility}}^2 = \max\{0, (\tilde{\theta}_O + (p-1)\tilde{\theta}_{PO} - p\tilde{\theta}_E)/pr\}$
$\sigma_M^2 = \sigma_O^2 + \sigma_{PO}^2 + \sigma_E^2$	$\tilde{\sigma}_M^2 = \frac{\tilde{\theta}_O + (p-1)\tilde{\theta}_{PO} + p(r-1)\tilde{\theta}_E}{pr}$
σ_P^2	$\hat{\sigma}_P^2 = \max\{0, (\tilde{\theta}_P - \tilde{\theta}_{PO})/or\}$
$\gamma = \sigma_P^2/\sigma_M^2$	$\tilde{\gamma} = \tilde{\sigma}_P^2/\tilde{\sigma}_M^2$

where the χ_d^2 are independent χ^2 random variables and the lower case s^2 are realized values of the mean squares S^2 .

- For each R&R measure, using its definition (column 2 of Table 2), we replace each EMS by its GPQ in step 1, taking care to assign zero for negative values of GPQ. This produces the GPQ for R&R measures in column 2 of Table 3.
- Next we use simulation to obtain the 100($\alpha/2$)th and 100(1 - $\alpha/2$)th percentile of these GPQ as 100(1 - α)% GCI: simulate N independent values for each of $\chi_{(p-1)}^2$, $\chi_{(o-1)}^2$, $\chi_{(p-1)(o-1)}^2$, and $\chi_{po(r-1)}^2$. Use these to compute N values of each GPQ in Table 3. For each GPQ, we order the N values in ascending order. The $N(\alpha/2)$ th value and $N(1 - \alpha/2)$ th value in the ordered set of each GPQ is the required GCI.

Compared to MLS CI, the GCI procedure does not have explicit expression and requires computer simulation which will subject its estimates to simulation variation. Fortunately, this variation can be controlled by having a large enough value of N . It is recommended to use $N \geq 100000$. The attractiveness of GCI lies in its ability to provide CI where MLS methods are not available due to either complex functions or complex R&R study designs. For instance, Burdick *et al.* [14] propose CI for misclassification probabilities. In other situations, the GCI method can be easily applied to complex gauge R&R studies involving three factors with a nested structure such as that described by Burdick and Larsen [5].

Extension to Mixed Effects and Unbalanced Data Models

We have considered only the R&R studies where the operators and parts are regarded as random

effects as they have been randomly selected from the population at large. Daniels *et al.* [15] consider R&R studies with operators as fixed effects as they have been selected from a relatively small population. They proposed MLS and GCI intervals and showed by simulation studies that the GCI intervals are to be recommended over the MLS as they are sometimes much shorter. Another extension from our discussion concerns the balance/unbalance data nature of R&R study. A balanced data set has equal replications for each part by operator combination. Sometimes, due to practical reasons such as gauge malfunction during a study, unequal replications can occur resulting in unbalanced data. Consequently, the MLS and GCI methods described earlier, which assume balanced ANOVA and weighted **sum of squares**, cannot be applied. Instead, unweighted sum of squares (USS) are employed for the MLS and GCI approach. Gong *et al.* [16] consider CI for unbalanced two-factor gauge R&R studies.

A summary of earlier MLS related methods for mixed effects/unbalanced data models is found in Burdick and Graybill [12] while a comprehensive discussion and examples using MLS and GCI can be found in Burdick *et al.* [10].

ANDY KOK LEONG CHIANG

Measurement Error and Uncertainty

Introduction

Measurement systems analysis (MSA) involves understanding the measurement process in place, identifying and estimating the error present in the process or system, and determining the adequacy of the **measurement system** for use in product and **process control** (see **Engineering Process Control**). A measurement system itself consists of devices to obtain measurements (gauges), standards, methods, personnel, and so on. That is, it is the entire process for obtaining measurements on some quantity of interest (*measurand*). *Error* and *uncertainty* will be a part of any measurement system or in the results from any measurement system put into place. Unfortunately, the concepts of error and uncertainty are often confused with one another and sometimes used (incorrectly) interchangeably. There are two (if not more) schools of thought with respect to the operational definitions of error and uncertainty. In this chapter, measurement error, uncertainty, and their components are presented as they are often used and defined in the literature [1–6]. In addition, definitions and relationships for precision and accuracy with respect to measurement systems are provided.

Error

Error is by definition the difference between the measured value of the quantity of interest (*measurand*) and the true value of the measurand. In the literature, error has also been referred to and written as *measurement error*, *error of measurement*, *experimental error*, and so forth; although depending on the experimental situation, these terms may have specific and therefore, quite different meanings. In addition, issue has sometimes been taken with the use of the term *true* value of the measurand (see [3, 4, 7] for example), since a true value is unknowable. “Reference value” is often used interchangeably with true value although this use is not recommended [8]. The reference value should be considered more as the best *approximation* available for the true value.

There are numerous types of error. These may include random error, systematic error, observer

error, repeatability error, discrimination error, total error, and rounding error, just to name a few (see [6]). In this section, two important and common types of error are presented as well as their use in MSA: systematic error and random error.

Systematic Error

Systematic errors can be caused by human activities, inadequate manufacturing methods, imperfections of the measuring device, changes in temperature, pressure, and so on. This error remains the same over repeated measures taken under identical conditions. That is, the error that is induced for one measurement will be identical to the error for the next measurement. The error is *systematic* and results in values that are consistently above or consistently below the true or reference value of the measurand. Systematic error can also be defined as the difference between error and random error (discussed in the next subsection).

Random Error

Suppose that repeated measures are taken on the same item, under identical conditions (same operator, same gauge). Under ideal conditions, even when systematic errors have been identified and accounted for, error will occur. *Random errors* vary randomly over all measurements taken under identical conditions. Even in a well-designed experiment or well-designed MSA, normal random fluctuations will occur and often occur according to some distribution (usually a Gaussian distribution with zero mean). If only random errors exist in the system, then increasing the number of measurements taken will provide a better estimate or better approximation of the measurand’s true value. For example, if the average of the measurements taken is the best estimate for the true value of the measurand, then increasing the number of measurements will result in a better estimate.

Measurement Results Modeled by Systematic and Random Errors

Suppose that the following could represent a measurement result

$$Y = X + \varepsilon \quad (1)$$

2 Measurement Error and Uncertainty

where Y is the measurement result, X is the true value of the measurand, and ε represents the combination of both systematic and random error. If the error is combined to represent both the systematic and random error, and we let ν represent the mean of ε and σ^2 the variance, then it can be said that $\varepsilon \sim (\nu, \sigma^2)$. In this form, if $\nu = 0$ then the measurements are considered more *accurate* and there is no “systematic error”. Furthermore, if σ is sufficiently small, the measurements are considered more *precise*. (For more details, the reader is encouraged to see [9]). Precision and accuracy play a very important role in MSA and are discussed in the next subsection.

Measurement System Error

Measurement system error as it pertains to MSA (see **Measurement Systems Analysis, Overview**) is a combination of variability attributable to gauge *bias*, *stability*, *linearity*, *repeatability*, and *reproducibility* (see **Gauge Repeatability and Reproducibility (R&R) Studies; Gauge Repeatability and Reproducibility (R&R) Studies, Variance Components in; Gauge Repeatability and Reproducibility (R&R) Studies, Misclassification Rates; Gauge Repeatability and Reproducibility (R&R) Studies, Confidence Intervals for**). Bias, linearity, and stability are the components that make up the *accuracy* of a measurement system. Repeatability and reproducibility are the components that make up the *precision* (measurement variation).

Accuracy. *Accuracy* is defined as the difference between the measurement and the value of the measurand. Accuracy is a qualitative concept and, as a result, is not quantifiable. It does not make sense to describe a measurement system in these terms by saying, for instance, “the accuracy is 0.05 cm”. *Uncertainty* (discussed in the section titled “Uncertainty”), however, is quantifiable and can be used to describe the system: “The standard uncertainty is 0.05 cm.” In measurement system error, the three components of accuracy and their definitions are

- *Bias* – the difference between the observed average measurement and a reference or master value. It is a measure of the systematic error with respect to the measurement system.
- *Linearity* – measures how changes in the size of the measurand (part being measured) will affect

measurement system bias over the expected range of the process.

- *Stability* – measures how well the measurement system performs over time. It reflects the change in bias (if any) over time when the same parts or master value are measured.

In general, accuracy focuses on measures of location or the relationship between the measurement results and value of the measurand.

Precision. *Precision* is defined as the variation identified when the same part or item is measured repeatedly using the same measurement device or gauge. The components of precision are listed below (see **Measurement Systems Analysis, Overview; Gauge Repeatability and Reproducibility (R&R), Variance Components in; Gauge Repeatability and Reproducibility (R&R) Studies, Misclassification Rates; Gauge Repeatability and Reproducibility (R&R) Studies, Confidence Intervals for**).

- *Repeatability* – variability due to the gauge or test instrument when used by the same operator to measure the same unit. In other words, this is variability arising from the same operator (or setup) measuring the same part repeatedly using the same measuring device (gauge).
- *Reproducibility* – variability due to different operators or setups measuring the same parts using the same measuring device (gauge). This is considered the variability due to the measurement system.

Summary of Error

Chunovkina [3] among others argues that error is a model concept and as a result cannot be used to directly calculate error. Arguments have been made that error differs conceptually from uncertainty and as a result these terms should be used cautiously. Full and excellent discussions on measurement error can be found in [3, 4, 6, 9]. Measurement system error is discussed in [7].

In the next section, measurement uncertainty is presented. The discussion is based on several articles that discuss the *Guide to the Expression of Uncertainty in Measurement* (1993) also known as *GUM*, as well as the guide itself. In addition, the reader is encouraged to see *Guidelines for Evaluating*

and Expressing the Uncertainty of NIST Measurement Results [2].

Uncertainty

The International Committee for Weights and Measures (CIPM) in conjunction with several international organizations, including the International Engineering Consortium (IEC) and International Organization for Standards (ISO) began work on a project that would hopefully result in some common approach for describing the quality of measurement results among international laboratories. The result of this project is the GUM published in 1993. GUM attempts to provide a conceptual framework for assessing and reporting uncertainty in measurements. In this section, uncertainty and its extensions are presented. The reader is encouraged to see GUM as well as [2–5, 10] for full details and discussion of uncertainty as well as some critiques of GUM itself [3].

Standard Uncertainty

As stated previously, MSA as a whole is used to understand the measurement system and attempt to improve it through variation reduction techniques. *Standard uncertainty* on the other hand attempts to *quantify* the range of measurement values by providing intervals over which the measurement results would vary with a certain probability (or in some instances confidence levels). The expectation is the value of the measurand would be captured by this interval. Technically, uncertainties are characterized by standard deviations (*see Variance*).

The purpose of the GUM (1993) was to provide comprehensive and consistent information on how to report measurement uncertainty. GUM also provided a common framework for comparison of measurement results internationally. GUM states that the uncertainty of a measurement is a “... parameter, associated with the result of a measurement that characterizes the dispersion of the values that could reasonably be attributed to the measurand”. Again, standard uncertainty, u_i , is described by standard deviation. Obviously, u_i is also the positive square root of u_i^2 . Components that make up uncertainty (to be discussed in this section) are categorized into one of two categories (this is the categorization

presented by [1]). Grouping of components depends on the method used to estimate numerical values. There are two types of uncertainties, type A and type B:

- *Type A* – based on statistical analysis of a series of measurements.
- *Type B* – based on other sources of information. These “other” sources can include, for example, gauge manufacturer’s specification or published reference values.

The definitions given here are very simplistic and the reader is encouraged to see [1, 2]. In the remainder of this section, more basic definitions and descriptions for uncertainty are provided.

Combined Standard Uncertainty

Combined standard uncertainty, u_c , is the standard deviation of the combined errors. These errors include both random error and systematic error. The combined uncertainty, u_c can often be obtained using the *law of propagation of uncertainty* when the measurand, Y is a function of several independent variables. For more details, see [9] or [2, Appendix A].

In MSA for example, the combined uncertainty would be a combination of all sources of measurement variation for that particular experimental situation. This would include measurement variation in the measurement process, **calibration** issues, environment errors, and so on. (See [7] for more discussion of measurement uncertainty in MSA.) To illustrate, suppose that the sources of variation for a particular process include repeatability, reproducibility, and stability denoted by $\sigma_{\text{repeatability}}^2$, $\sigma_{\text{reproducibility}}^2$, and $\sigma_{\text{stability}}^2$, respectively. The combined uncertainty would then be

$$u_c = \sqrt{\sigma_{\text{repeatability}}^2 + \sigma_{\text{reproducibility}}^2 + \sigma_{\text{stability}}^2} \quad (2)$$

There can be many situations where the combined uncertainty can be quite complicated [2, 10] and the law of propagation of uncertainty can be very useful.

Expanded Uncertainty

Often in measurement studies it is not enough to simply report a single combined estimate of uncertainty. An interval about the measurement results that

defines the measurement uncertainty is often required. *Expanded uncertainty*, U , is the combined standard uncertainty, u_c multiplied by some “coverage factor”, k . In other words, $U = ku_c$. The coverage factor, k , is chosen such that a certain level of confidence (see **Confidence Intervals**) (for Gaussian or normally distributed measurements in a measurement system) is attained. In all instances, the factor k results in a certain coverage interval. When the normal distribution applies (see **Normal Distribution; Normality Tests**), $k = 2$ will result in an approximate 95% **confidence interval**. Suppose a measurand, Y , is estimated by some value y . The combined uncertainty would be given by $u_c(y)$, then $U = ku_c(y)$ and the expanded uncertainty would be written as $Y = y \pm U$. The expanded uncertainty provides more information about the process than a single-number statistic.

Other Considerations and Standards

To attain some level of standardization and agreement among laboratories internationally, GUM (1993) has provided guidance on how to evaluate and express measurement uncertainty. The guide is a high-level reference document with some very broad and sweeping specifications and definitions. Some very basic definitions are given in this section and the reader is encouraged to review [1–5] for more complete discussions and illustrations of the concepts outlined here.

Summary and Conclusions

In this article, some very basic definitions and concepts concerning measurement error and uncertainty are provided. There remains a great deal of room in the literature for further discussion and clarification; not only for the benefit of the measurement community, but for any practitioner or entity that must rely on measurement results, MSA, and the inferences that are to be made from the results obtained.

It is also important to note that many of the terms and concepts presented here and in the literature may

take on different meanings and interpretation based on the experimental situation at hand. For instance, a source of random error in one experimental setup may easily be a systematic error in a different setup. The roles of error and uncertainty may be quite different depending on the type of measurements actually recorded, and their use in practice. Again, the reader is encouraged to review the references provided here and the references provided within those documents.

CONNIE M. BORROR

Measurement Systems Analysis, Capability Measures for

Introduction

There are two “families” of measurement capability metrics in common use. There are those that compare measurement variation to total or part variation, and there are those that compare to the tolerance or specification width. These capability metrics are all functions of the **variance components** in the statistical model used to describe the response of interest. In addition to these capability metrics, it is also often useful to estimate the misclassification rates that arise from using the measurement system to discriminate between “good” and “bad” items being tested. An additional capability metric is obtained from the ratio of the estimated misclassification rates to the rates that would occur purely due to random chance. This section will define several capability measures, how they are related to one another, and give some common criteria for capability. Additional topics discuss the effect of the unit of measure and present a situation where none of the aforementioned metrics are particularly useful in quantifying the capability of a measurement process.

Standard MSA

The standard experiment for conducting a measurement systems analysis (**MSA**) uses a two-factor design with “parts” and “operators”. The “parts” can be almost anything for which a measurement is desired – people on whom a medical test is performed, metal rods for which the length is desired, or cell phones to determine if the functionality is working properly. “Operators” can be the people doing the measurement or can be different gauges or measurement systems. The statistical model used to describe the response is the random two-factor model

$$Y_{ijk} = \mu + P_i + O_j + PO_{ij} + E_{ijk} \quad (1)$$

$$i = 1, \dots, p; \quad j = 1, \dots, o; \quad k = 1, \dots, r$$

where μ is a constant, and P_i , O_j , PO_{ij} , and E_{ijk} are jointly independent normal random variables with means of zero and variances σ_P^2 , σ_O^2 , σ_{PO}^2 , and σ_E^2 , respectively. These variance components are used to compute the measurement capability measures. A number of authors discuss how to estimate variance components in the random two-factor model (see, e.g. [1]).

Commonly Used Capability Measures

The primary purpose of MSA is to determine whether the measurement process is adequate for its intended use. This is typically done by comparing the estimated measurement variation to either the part or total variation or to the width of any applicable tolerances or specifications.

Table 1 provides parameters of interest for assessing the capability of a measurement process. Table 2 presents some commonly used capability metrics. Perhaps the most common capability metric is the precision-to-tolerance ratio (PTR). The PTR is defined as:

$$PTR = \frac{k\sqrt{\gamma_M}}{USL - LSL} \quad (2)$$

where USL and LSL are upper and lower specification or tolerance limits and k is either 5.15 or 6. The value of $k = 6$ corresponds to the middle 99.73% of a normal probability distribution and $k = 5.15$ corresponds to the middle 99%. PTR compares the total measurement variation to the width of the specifications or tolerances the items being measured are to adhere to. The Automotive Industry Action Group (AIAG) MSA manual [2] recommends the following criteria be used for PTR:

$PTR \leq 0.1$: the measurement process is capable;
 $0.1 < PTR \leq 0.3$: the process is marginal;
 $PTR > 0.3$: the process is not capable.

It is further recommended that a confidence level be placed on the PTR to reflect the uncertainty associated with estimating variance components. For example, for the measurement process to be capable, the PTR should be less than 0.1 with at least a 90% level of confidence. Burdick *et al.* [3] give methods for computing **confidence intervals** on a variety of MSA metrics.

It has been noted in several places (see, e.g. [4]) that the PTR does not necessarily provide a

2 Measurement Systems Analysis, Capability Measures for

Table 1 Parameters of interest in MSA

Parameter	Variance component(s)	Definition
γ_P	σ_P^2	Variance among parts
γ_M	$\sigma_O^2 + \sigma_{PO}^2 + \sigma_E^2$	Total measurement variation
$\gamma_T = \gamma_P + \gamma_M$	$\sigma_P^2 + \sigma_O^2 + \sigma_{PO}^2 + \sigma_E^2$	Total variation
$\gamma_R = \gamma_P / \gamma_M$	$\sigma_P^2 / (\sigma_O^2 + \sigma_{PO}^2 + \sigma_E^2)$	Ratio of part to measurement variation
$\rho_P = \gamma_P / \gamma_T$	$\sigma_P^2 / (\sigma_P^2 + \sigma_O^2 + \sigma_{PO}^2 + \sigma_E^2)$	Ratio of part to total variation
$\rho_M = \gamma_M / \gamma_T$	$(\sigma_O^2 + \sigma_{PO}^2 + \sigma_E^2) / (\sigma_P^2 + \sigma_O^2 + \sigma_{PO}^2 + \sigma_E^2)$	Ratio of measurement to total variation

Table 2 Common capability metrics

Metric	Definition	Criteria
PTR	$\frac{k\sqrt{\gamma_M}}{USL - LSL}$	$k = 5.15$ or 6 $PTR \leq 0.1$: capable $0.1 < PTR \leq 0.3$: marginal $PTR > 0.3$: not capable
SNR	$\sqrt{2\gamma_R}$	$SNR > 10$: excellent $5 < SNR \leq 10$: acceptable $SNR < 5$: unacceptable
$PTV = \%R\&R$	$\sqrt{\rho_M} \times 100\%$	$PTV \leq 10\%$: excellent $10\% < PTV \leq 30\%$: acceptable $PTV > 30\%$: unacceptable
DR	$\sqrt{\frac{1 + \rho_P}{1 - \rho_P}}$	$DR > 4$: acceptable $2 < DR \leq 4$: marginal $DR < 2$: unacceptable

good indication of how well the measurement system performs for a particular process. This is due to the relationship between the capability of the production process and the capability of the measurement system used to monitor the production process. When the production process is highly capable of meeting the production limits, it can tolerate a higher PTR than a production process which is not capable. It is therefore useful to compute other measurement capability metrics that compare the measurement variation to total or part variation.

The signal-to-noise ratio (SNR) is defined as:

$$SNR = \sqrt{2\gamma_R} \quad (3)$$

The AIAG MSA manual defines SNR as the number of distinct data categories that can be reliably distinguished by the measurement system. A value of 5 or greater is recommended. Based on experience over a number of years, the author recommends the following criteria be met with at least a 90% level of confidence:

$SNR > 10$: the measurement process is excellent;
 $5 < SNR \leq 10$: the process is acceptable;
 $SNR < 5$: the process is unacceptable.

Another commonly used metric in the same class is the percent of total variation (PTV) or equivalently the percent of reproducibility and repeatability (%R&R). The PTV is defined as:

$$PTV = \sqrt{\rho_M} \times 100\% \quad (4)$$

AIAG recommends criteria of:

$PTV \leq 10\%$: the measurement process is excellent;
 $10\% < PTV \leq 30\%$: the process is acceptable;
 $PTV > 30\%$: the process is unacceptable.

Again, the author further recommends that the PTV be bounded by confidence intervals and the criteria be applied using at least a 90% confidence level.

Another metric in the same class is the discrimination ratio (DR) (see [5] or [6]). The DR is defined

as:

$$DR = \sqrt{\frac{1 + \rho_P}{1 - \rho_P}} \quad (5)$$

ρ_P is the intraclass **correlation** defined as the correlation between two measurements taken on the same part. Mader *et al.* [5] suggest the following criteria:

$DR > 4$: the measurement process is acceptable;
 $2 < DR \leq 4$: the process is marginal;
 $DR < 2$: the process is unacceptable.

An additional recommendation is that DR be bounded by confidence intervals and at least a 90% confidence level be used to judge the capability of the measurement process.

Interrelationships among Capability Metrics

$$PTV = \frac{100}{\sqrt{\frac{SNR^2}{2} + 1}} \quad SNR = \sqrt{2 \left(\frac{100^2}{PTV^2} - 1 \right)}$$

$$\rho_P = \frac{SNR^2}{SNR^2 + 2} \quad SNR = \sqrt{\frac{2\rho_P}{1 - \rho_P}}$$

$$DR = \sqrt{SNR^2 + 1} \quad SNR = \sqrt{DR^2 - 1}$$

Using Misclassification Rates to Determine Capability

In a “test” situation where the measurement system is used to discriminate among items such as a medical test for disease or a functional test for cell phones, Burdick *et al.* [3] have suggested a misclassification index for assessing capability. The misclassification rates or test errors are sometimes called *false failures* and *missed faults* or *false positives* and *false negatives*. The misclassification rates are directly analogous to the type I (α) and type II (β) errors in statistical **hypothesis testing**. Methods to estimate the misclassification rates have been described by several authors (see, e.g. [7]) and include numerical integration and computer simulation.

Suppose we wish to test a product to determine whether or not it meets acceptable limits.

In the case of two-sided test limits and specifications, the situation appears as in Figure 1. Following the notation in [7], define the following terms:

Y = true value $\sim N(\mu_P, \gamma_P)$
 X = measured value $= Y + E$
 E = measurement error $\sim N(0, \gamma_M)$
 $f(x, y)$ = joint pdf
 $f(x)$ = marginal pdf for X
 $f(y)$ = marginal pdf for Y

SL and SU are the lower and upper product specifications

TL and TU are the lower and upper test limits.

The test limits may or may not be equal to the product specifications.

The following probabilities are obtained by numerical integration or computer simulation.

$$P(\text{Bad}) = \int_{-\infty}^{SL} f(y) dy + \int_{SU}^{+\infty} f(y) dy = 1 - \pi \quad (6)$$

$$P(\text{Fail}) = \int_{-\infty}^{TL} f(x) dx + \int_{TU}^{+\infty} f(x) dx \quad (7)$$

$$P(\text{Pass, Bad}) = \text{Joint MF} \\ = \int_{-\infty}^{SL} \int_{TL}^{TU} f(x, y) dx dy$$

Figure 1 Misclassification rates with two-sided test limits and specifications

4 Measurement Systems Analysis, Capability Measures for

$$+ \int_{SU}^{+\infty} \int_{TL}^{TU} f(x, y) dx dy$$

$$= \beta \quad (8)$$

Both conditional and joint misclassification rates are obtained using Bayes formula and some algebra.

$$P(\text{Fail}|\text{Good}) = \text{FF}$$

$$= \frac{P(\text{Fail}) - P(\text{Bad}) + P(\text{Pass}, \text{Bad})}{1 - P(\text{Bad})}$$

$$= \alpha_c \quad (9)$$

$$P(\text{Pass}|\text{Bad}) = \text{MF} = \frac{P(\text{Pass}, \text{Bad})}{P(\text{Bad})} = \beta_c \quad (10)$$

$$P(\text{Fail}, \text{Good}) = \text{Joint FF}$$

$$= \text{FF}(1 - P(\text{Bad})) = \alpha \quad (11)$$

The joint misclassification rates, α and β are typically reported because they are relevant to the whole population of products.

When considering whether the misclassification rates are sufficiently small, Burdick *et al.* [3] have suggested comparing them to what could be obtained by chance. The proposal goes as follows. Suppose the value of π , $P(\text{Good})$, in equation 6 is known. A chance process for classifying parts is to take no measurements and randomly classify π of the parts as good and $1 - \pi$ as bad. For this chance process, the probability of a false failure is

$$\alpha^* = P(\text{Fail}, \text{Good})$$

$$= (1 - \pi)\pi \quad (12)$$

Likewise, the probability of a missed fault for this chance process is

$$\beta^* = P(\text{Pass}, \text{Bad})$$

$$= \pi(1 - \pi) \quad (13)$$

Thus, for a measurement system to be useful, the misclassification rates α and β should be less than what could be obtained by chance, α^* and β^* . A similar argument can be made for the conditional probabilities α_c and β_c . In this case, the conditional probabilities that could be obtained by chance are $\alpha_c^* = 1 - \pi$ and $\beta_c^* = \pi$.

Burdick *et al.* [3] proposed the following indices be used to assess the capability of the measurement system to discriminate good product from bad.

$$\alpha_{\text{index}} = \frac{\alpha}{\alpha^*} \quad (14)$$

$$\beta_{\text{index}} = \frac{\beta}{\beta^*} \quad (15)$$

And since $\alpha_c/\alpha_c^* = \alpha_{\text{index}}$ and $\beta_c/\beta_c^* = \beta_{\text{index}}$, these indices can be used for both the conditional and joint definitions of misclassification rates. The criteria for establishing the capability of the measurement process is for both α_{index} and β_{index} to be less than unity with at least a 90% confidence level. Burdick *et al.* [3] suggested using generalized confidence intervals and Larsen [7] proposed a different computer simulation method which provides similar results.

Effect of the Unit of Measure

Experience has shown that SNR and PTR are largely scale invariant so long as the data do not contain **outliers**. For example, decibel (db) is a common unit for electrical measurement. Decibel can be defined as the log of the ratio of two voltages. Whether the MSA is conducted directly in decibel units or with a linearizing transformation does not matter in so far as the capability measures are concerned so long as the data do not contain outliers. SNR and PTR values will be similar either way. Doing the analysis both with raw and transformed data and finding a large difference in either SNR or PTR often indicates the presence of outliers. And these outliers should be examined for validity and possible exclusion from the MSA.

A Situation Where the Usual Metrics Can Be Noninformative

It is increasingly the case in testing consumer electronic devices (cell phones, PDAs, etc.) that the measurement system is used to “align” the device rather than determine whether it performs within acceptable limits. With alignment, the value the device initially has is unimportant because the measurement system changes the value of the device to lie within a narrow range. When device parameters are aligned, the

resulting “part” variation is similar to that found in the measurement system. This implies that the SNR will tend to be well below the usual criteria of 5. Further, parameters which are aligned do not have test limits in the usual sense because the objective is not to determine pass or fail but rather to set the parameter to a predefined value or narrow range of values called *alignment limits*. The alignment limits are a trade-off between providing a sufficient margin with industry standard specifications and aligning to a nominal value that often takes excessive test time. The object of the alignment is not to center the parameter within the limits but just to get within them. Often there are no product specifications warranted to the end customer on aligned parameters of consumer electronic devices. This situation makes the PTR difficult to apply as well. Using the alignment limits in the denominator of the PTR typically provides values too high to meet the usual criteria. Finally, because the measurement system is not used to determine pass or fail, the misclassification indices are not applicable.

The question of how to assess the capability of a measurement system used to align parameters is difficult to answer. Larsen [8] makes several recommendations which include comparing the total measurement system variability found from an MSA to a tolerance stack of component tolerances in the measurement system. If the measurement variability from the MSA is less than the value from the tolerance stack, then the measurement process is at least meeting capability expectations. However, as noted, this is no guarantee that the measurement system is adequate in a particular application. It is also suggested that the measurement equipment be calibrated and traceable to National Institute of

Standards and Technology (NIST) so that system-to-system variation is lessened. Finally, the PTR might be applicable if the alignment limits are used with relaxed criteria or if product specifications are developed which reflect acceptable functional performance to the end customer.

GREG A. LARSEN

Gauge Repeatability and Reproducibility (R&R) Studies, Destructive Testing

Gauge R&R Study

Measurement results can never simply be taken for granted. Often it's impossible to be absolutely sure, even if you are willing to investigate the measurement in depth. The practical solution for this dilemma is to examine how the measurements are obtained, and to release the procedure for future use if some well established conditions are satisfied. *Truth* and *precision* are the two aspects of measurement, dealing with the average and variation respectively. The standard method for assessing the precision of a **measurement system** is the *gauge repeatability and reproducibility study* (gauge R&R study, **Gauge Repeatability and Reproducibility (R&R) Studies**), for measurements on a numerical scale. The basis is a designed experiment with repeatedly measured objects, but the consequence is that the gauge R&R study is useless for so-called destructive measurements. Some measurement procedures are destructive in nature, e.g., when the strength of a product is obtained by recording the force needed to break it. Other measurements cannot be repeated because the measured object is constantly changing, e.g., the density of a flowing liquid in a pipeline. Both types of measurement are called *destructive*, even though the second example shows that this is not necessarily true for the measured objects.

The standard gauge R&R study uses the property that object-to-object variation can be distinguished from measurement variation, by repeating the measurements of a single object. For destructive measurements the two sources of variation are confounded. The only way to separate them is to make assumptions about the nature of the measurements, or the measured objects. For an investigation of strength measurements, you might carefully select a number of apparently equal products, and then assume that all variation in strength is measurement variation. We summarize all possible assumptions, and show how to analyze in each case.

Consequences for Destructive Measurements

The result of a gauge R&R study is an estimate of the measurement precision. If measurement variation is small compared to process variation or product tolerance width, then we decide that for our intentions the measurement is sufficiently precise. Destructive measurements usually lead to overestimation of the measurement precision. With the strength measurements above, for example, any product-to-product variation is wrongly attributed to the measurement precision. In some cases we might therefore falsely reject the measurements as too imprecise. Note that this protects us against undue optimism. The validity of the assumptions plays a crucial role, of course, whether or not measurement precision is estimated well.

Measurement

Measurement allows for mathematical study of interesting properties of objects or experimental units. A formal definition of a measurement of a property of a unit is the assignment of a numeral to that unit, reflecting the classification of the units according to the property under study. In this article we assume that the measurements use a numerical scale. But certainly in the context of destructive measurements we have to realize that objects may evolve in time. For this reason we choose to consider a single object at two different moments in time as two different experimental units. The density of the liquid in a pipeline at moment t is probably different from the density at t , when owing to the flow the liquid is not exactly the same or even completely different. This is reflected by the assumption that we are dealing with different experimental units. The mathematical definition of a measurement is the map $Y : U \rightarrow R$, with U consisting of elements u_{it} (the index i denotes experimental unit i and t refers to moment t) and R is the set (or a subset) of real numbers.

Assumptions for the Standard Gauge R&R Studies

The conditional probability distribution $F(Y|u)$ of Y given $u \in U$ defines the random measurement error. A measurement system is *accurate* when the conditional expectation of $F(Y|u)$ coincides with the true value $T(u)$. The difference is called the *bias*. Accuracy is investigated with **calibration** methods, and is

2 Gauge R&R Studies, Destructive Testing

separated from gauge R&R studies. Nevertheless we need to assume one important condition:

(a) The bias is constant for every $u \in U$ (linearity) and constant in time (stability).

The *precision* of a measurement system relates to the conditional standard deviation of $F(Y|u)$. Usually this variation is independent of the measured units. If this cannot be assumed, then a gauge R&R study yields nonsense, unless the relation between the variation and the object can explicitly be stated. Some measurements have different values for precision in different ranges, for example because different electrical components (such as resistors) are used. The solution is then to do separate gauge R&R studies for different ranges, while assuming a constant variation within one study. In this article we assume *homogeneity of measurement error*:

(b) $F(Y - \mu_{it}|u_{it}) = F(Y - \mu_{js}|u_{js})$ for all u_{it} and u_{js} (and μ is the conditional expectation).

This condition implies that the variation is independent of the measured unit.

Our formulation of measurements indicates a fundamental problem: for a fixed u_{it} normally no more than one realization of $Y(u_{it})$ is possible, prohibiting **estimation** of the variation of $F(Y|u_{it})$ without making additional assumptions. For standard gauge R&R studies two additional homogeneity assumptions are made. The first is the *temporal stability of objects*, meaning that it doesn't matter when the object is measured:

(c) For every object u_i the true value is constant in time: $T(u_{it}) = T(u_{is})$ in a relevant time interval.

The second assumption is *robustness of measurement*, meaning that the examined property of the object is not affected by the measurement:

(d) $T(u_{it})$ is equal before and after object u_i is measured.

Repeated measurements of object u_i can be used to estimate the variation of $F(Y|u_i)$ if assumptions (c) and (d) hold. For the standard gauge R&R study you normally select a few (say 10) representative objects, and pool the estimates of the variation for the separate objects (see **Gauge Repeatability and**

Reproducibility (R&R), Variance Components in for the details).

Assumptions for Gauge R&R Studies of Destructive Measurements

If at least one of the assumptions (c) or (d) does not hold, then the measurement is *destructive*. To resolve the fundamental problem of gauge capability studies, other – more stringent – assumptions are needed for estimating the measurement variation. These assumptions can be summarized according to Table 1.

Gauge R&R Studies for Destructive Measurements

In this section we identify a number of situations in which a satisfactory approach is available for conducting a gauge R&R study for destructive measurements.

Temporal Stability; Object Variation is Known

The first situation we consider is that assumption (c) holds, but assumption (d) does not: the objects u_i we want to measure do not change over a relevant time period except when they are measured. An estimate of the measurement variation requires therefore several objects, because each object can be measured only once. Unless the variation of the objects themselves is known, we still have no possibility to separate measurement variation from objects variation. Three possible solutions are given.

Table 1 Assumptions for Gauge R&R Studies

	Temporal stability (assumption (c) is true)	No temporal stability
Robust measurement (assumption (d) is true)	Standard gauge R&R study	Temporal variation can be modeled (j)
Nonrobust measurement	Objects variation known (e, f, g) Alternative measurements available (h, i)	True values known (k)

Homogeneity of Objects.

(e) There is a subset $H \subset U$ with $T(u_i) = T(u_j)$ for all u_i and u_j in H .

The first solution is applicable if you can select a number of objects with identical true value, regarding the interesting property. In a production process you may assume that products made from the same batch of raw materials, and in a small period of time, are quite alike. For the investigation of a strength test such products are obvious candidates to fulfill assumption (e). Under this condition the variation of the measurements of the objects $u_i \in H$ is the measurement precision.

Representativeness of Alternative Objects. Assumption (e) might be wishful thinking: some measured objects are inherently variable. For a gauge R&R study, which is not daily practice, we might use alternative objects instead, objects satisfying condition (e) and representative of the normal measurements. Generally speaking, this assumption is a solution when ordinary measured objects can favorably be replaced by better-defined objects. For a measurement capability study of the strength of wired diodes, it is better to replace the diodes by simple wires with strengths comparable to the diodes, because their homogeneity is much easier to control.

(f) There is a set of alternative objects $A = \{v_i\}_{i=1,\dots,k}$ for which the homogeneity condition (e) does hold, and with the same probability distribution F , i.e., $F(Y - \mu_u|u) = F(Y - \mu_v|v)$, for all $v \in A$ and any $u \in U$.

Under assumption (f) the variation of the measurements of the alternative objects is the measurement variation we are looking for.

Patterned Objects Variation. If there is no set of objects (or substitutes) for which homogeneity can be assumed, then in several cases there is a possibility to artificially create a homogeneous set by correcting for modeled heterogeneity.

(g) For all u_i in a subset $H \subset U$ the true value $T(u_i) = f(u_i)$, f is a known function with a small number of unknown parameters.

Condition (g) essentially says that the variation of the objects is not random, but that a (partly) known

pattern can be discerned. Some useful examples of the functions f are:

- $f(u_k) = \beta_0 + \beta_1 k$ for gradually increasing or decreasing successive objects $u_1, \dots, u_n$.
- $f(u_k) = B_i + P_j$ for u_k from batch i and position j .

With a suitable selection of objects u_i from the subset H the unknown parameters of the function f can be estimated from the measurements $Y(u_i)$, and from this the true value $T(u_i)$ can be inferred. Under condition (g) the variance of measurement error can be estimated as $(n - p)^{-1} \sum_{i=1}^n \{Y(u_i) - \widehat{T}(u_i)\}^2$ with $\widehat{T}(u_i)$ the fitted true value, and p the number of unknown parameters of the function f .

Temporal Stability; Alternative Measurements are Available

The second situation we consider applies when the destructive measurement is a cheap or operator-friendly alternative of either a nondestructive measurement, or destructive measurement of higher quality. Both cases are described for the situation that objects do not change over a relevant time period.

An Alternative Nondestructive Measurement. If a nondestructive alternative measurement is available (maybe at the laboratory, or at a dedicated institute), then the measurement variation of the destructive method can be determined without taking recourse to the methods of the previous paragraphs. The assumption is:

(h) An alternative nondestructive measurement exists.

The way to proceed is straightforward. Select a sample of n objects, and measure them with the alternative method for a standard gauge R&R study. Apart from an estimate of the measurement variation of the alternative method, this yields an estimate of the variation of the true values of the selected objects. Then measure the same objects destructively, with the method we are investigating. The variation of these measurements is the combined effect of the objects themselves and measurement error. The variance minus the variance

of the object's true values is an estimate of the variance of the destructive measurement method. Note that we do not assume that the alternative method yields perfect measurements: a constant bias is allowed.

An Alternative Perfect Destructive Measurement.

(i) An alternative destructive measurement X exists for which $X(u_i) = T(u_i)$ for all objects $u_i \in U$.

The meaning of condition (i) is that the method under study can be replaced with a perfect destructive alternative, i.e., the true value could be obtained from this alternative method. The case of a perfect *nondestructive* alternative is even simpler, and would in effect come down to the situation that the true values of the objects are known. In case of condition (i) a sample of objects from U is randomly split in two subgroups. One subgroup is measured with the alternative method, and the variance is an estimate of the variance of the true values of the other subgroup. The variance of the measurements of the other subgroup, using the method under study, minus the variance of the object's true values, is an estimate of the variance of this method's measurement error.

Robust Measurement; Temporal Variation is Known

The third situation we consider is that the act of measuring has no influence on the object, but the objects themselves are constantly changing. If we know how to model this, then variation due to objects can be separated from variation due to measurement. This assumption, labeled *patterned temporal variation*, is very similar to assumption (g).

(j) For all u_{it} in a subset $H \subset U$ the true value $T(u_{it}) = f(u_{it})$, with f a known function with a small number of unknown parameters.

Assumption (j) merely states that the temporal variation is not just random, but that it follows a certain pattern.

The simplest "pattern" is that some objects can be selected with a constant true value in some period of time. A tank with a completely homogeneous liquid could be pumped through a pipeline. In this

period the density may assumed to be constant, so all variation in the density measurements can be regarded as measurement variation. Another common model for some u_i in H is $f(u_{it}) = \beta_{0i} + \beta_{1i}t$.

The way to proceed is to obtain measurements $Y(u_{it(j)})$ of object u_i at k moments $t(1), \dots, t(k)$. From these measurements the unknown parameters of the function f are estimated, which in turn yield estimates of the true values $T(u_{it(j)})$. Under condition (j) the variance of measurement error can be estimated by $(k - p)^{-1} \sum_{j=1}^k \{Y(u_{it(j)}) - \widehat{T}(u_{it(j)})\}^2$

with $\widehat{T}(u_{it(j)})$ the fitted true value, and p the number of unknown parameters of the function f . For a better estimate this procedure should be repeated for several objects u_i , and the estimated variances are pooled.

True Values are Known

The final and most restrictive case is that the true values of (some) objects are known. This is the standard assumption of ordinary calibration studies. Any measurement procedure reveals its secrets when this assumption holds for a *representative* set of objects.

(k) A set H of objects u_{it} exists for which $T(u_{it})$ is known, $\forall u_{it} \in H$, and H is representative for U (i.e., the condition in (f) about the probability distribution F holds as well).

Assuming an unbiased measurement Y , the measurement variance is simply estimated by $k^{-1} \sum (Y(u_{it}) - T(u_{it}))^2$. A known bias β can be simply be corrected for by replacing $Y(u_{it})$ with $Y(u_{it}) - \beta$. And if the bias is unknown, then $k^{-1} \sum (Y(u_{it}) - T(u_{it})) = \bar{Y} - \bar{T}$ is an estimate of β , and the sample variance of the $Y(u_{it}) - T(u_{it})$ estimates the measurement error.

Evaluation

The fundamental problem of gauge capability study is that no object can be measured more than once. In many cases the problem can be solved, however, by the assumption that objects are constant in time (assumption (c) in this article). But the less severe assumption that temporal variation can be modeled (assumption (j)) may also be sufficient, at least, if measuring does not influence the object's true value

(assumption (d)). If measuring is *destructive* in the sense that assumption (d) is violated, then assumptions (e–i) or (k) could help to quantify the measurement error.

The success of the gauge R&R study depends on two conditions: the effort of doing a good experiment, and the validity of the assumptions. A bad experiment can lead to any false conclusion, but the effect of only partially true assumptions is one sided. A valid assumption is a correct model of the object-to-object variation, and variation due to measurement can be perfectly distinguished – apart from sampling error. If an assumption is not correct, however, then the estimated measurement variation will contain (part of) the object-to-object variation, and will therefore be higher than the true value.

If, for instance, assumption (e) – there is a subset of identical objects – is assumed, but in reality $T(u_i) = \mu + \varepsilon_i$ with ε_i independent drawings from the $N(0, \sigma_\varepsilon^2)$ distribution, then the measurement variance σ_m^2 is estimated by the sample variance s^2 of the measurements $Y(u_i)$. But the expected value $E\{s^2\} = \sigma_m^2 + \sigma_\varepsilon^2$ confounds the measurement variance and the object-to-object variance σ_ε^2 .

Risk Analysis, Extremes in

General Background

In risk analysis, one often encounters situations where classical central limit theory does not extract all useful or even necessary information available in data. In such cases the extreme values in the sample might provide additional if not substantial insight into certain aspects of the data. The extremes in the sample deserve special attention, completing a thorough analysis of the available data. In specific cases, the extremes are even more vital than the central terms. For an early account on some of such issues, see the book by Gumbel [1]. More recent treatments that reflect the diversity of applications involved are given in Galambos *et al.* [2], Beirlant *et al.* [3], and Embrechts *et al.* [4].

In the section titled “Basic Extreme Value Theory” we will deal with the asymptotic theory for extremes coming from a classical statistical sample; this is by far the most encountered and best studied case. In the section titled “Statistical Aspects” we deal with some of the key statistical problems. The section titled “Discussion of Available Results” offers a discussion on adaptations and extensions of the offered material. In particular that section also refers to generalizations for which there already exists research literature. Applications are treated in **Applications of Extreme Statistics in Science and Engineering**.

Basic Extreme Value Theory

As explained, we first restrict ourselves to the case of independent and identically distributed (i.i.d.) random variables. In this way, the notational complexity can be kept to a minimum as it mimics that of traditional samples in statistics. Let $X_1, X_2, \dots, X_n$ be a sequence of independent random variables with a common distribution $F(x) = P\{X \leq x\}$ which is concentrated on an interval $-\infty \leq x_- \leq x_+ \leq \infty$ where x_+ (x_-) is the right (left) endpoint of the support of F .

With the above sequence we associate the sequence of *order statistics*

$$X_{n,1} \leq X_{n,2} \leq \dots \leq X_{n,n} \quad (1)$$

that will be crucial in what follows. To begin with, we focus our attention on the right tail behavior of F , hence to the maximum $X_{n,n}$.

The majority of properties of the extremes is controlled by the right tail behavior of F , expressed either in terms of its *quantile function* defined as the tail inverse of F by $Q(p) = \inf\{y : F(y) \geq p\}$ for $p \in (0, 1)$ or alternatively by the *tail (quantile) function* defined by $U(x) = Q(1 - \frac{1}{x})$ for $x > 1$.

De Haan’s treatise [5] lies at the origin of the revived interest in extreme value theory. There, the key challenge of extreme value theory is stated as the full solution of the *extremal domain of attraction problem*. By this we mean:

1. the derivation of all possible limit laws for $a_n^{-1}(X_{n,n} - b_n)$ where $\{a_n\}$ are positive norming constants while $\{b_n\}$ are real centering constants, and
2. the determination of the conditions on F that lead to one of the above limits.

The statement of this problem parallels that of the *central domain of attraction problem* where in the above the maximum $X_{n,n}$ is replaced by $S_n := \sum_{1 \leq i \leq n} X_i$. The solution to the first problem is offered by the class of *extreme value distributions* that can be written for $n \rightarrow \infty$ as

$$P\left(\frac{X_{n,n} - b_n}{a_n} \leq y\right) = F^n(a_n y + b_n) \longrightarrow \exp\left[-(1 + \gamma y)^{-1/\gamma}\right] =: G_\gamma(y) \quad (2)$$

for all y such that $1 + \gamma y > 0$. If Y_γ is a random variable with distribution G_γ then we write $a_n^{-1}(X_{n,n} - b_n) \xrightarrow{\mathcal{D}} Y_\gamma$. The parameter γ is called the *extreme value index* (EVI). It fully characterizes the distribution that clearly belongs to a one-parameter family of distributions.

The solution to the second problem depends on the value of the EVI: a distribution F belongs to the *domain of attraction* of the limit distribution G_γ (written in the form $F \in \mathcal{D}(G_\gamma)$) if and only if

$$\frac{\{U(xu) - U(x)\}}{g(x)} \longrightarrow h_\gamma(u) = \int_1^u v^{\gamma-1} dv \quad (3)$$

for all $u \geq 1$ as $x \rightarrow x_+$, for some *auxiliary function* $g > 0$. In general one can take $b_n = U(n)$ and $a_n = g(n)$. Equivalently, for some auxiliary function

2 Risk Analysis, Extremes in

$$b = g(1/(1 - F)),$$

$$\lim_{t \rightarrow x_+} \frac{1 - F(t + b(t)v)}{1 - F(t)} = (1 + \gamma v)^{-1/\gamma}, \text{ for all } v$$

with $1 + \gamma v > 0$ (4)

Unfortunately this streamlined result has not been at the roots of the development of extreme value theory. The one-parameter family $\{G_\gamma, -\infty < \gamma < \infty\}$ has been constructed as a reunification of three different types of extremal laws that have been separately discovered. Indeed, for the cases where $\gamma \neq 0$ one can make an additional affine transformation that simplifies the expression for the limit distribution at the cost of a loss of uniformity. More specifically

- Type I: $\gamma = 0$ is the most popular case and is called the *Gumbel case*. The domain $\mathcal{D}(G_0)$ contains most of the classical distributions like the normal, the lognormal, the gamma, and the Weibull distribution $1 - F(x) = \exp(-cx^\tau)$ with $\tau > 0$.
- Type II: $\gamma > 0$ leads to the *Pareto–Fréchet case* which is typical for heavy-tailed distributions. The prime example that actually characterizes $\mathcal{D}(G_\gamma)$ with $\gamma > 0$ is offered by the *Pareto-type distributions* where $1 - F(x) \sim x^{-1/\gamma} \ell(x)$ and ℓ is a slowly varying function. Often the extremal index γ is replaced by the *Pareto-index* defined by $\alpha = \gamma^{-1}$.
In this case the ratio $g(x)/U(x) \rightarrow \gamma$ so that also $a_n/b_n \rightarrow \gamma$. But then $X_{n,n}/U(n) \xrightarrow{\mathcal{D}} Z_\gamma$ and the limit law of Z_γ is slightly simpler than that of Y_γ .
- Type III: $\gamma < 0$ gives the *Weibull (extremal) case* which appears typically with distributions for which $x_+ = U(\infty) < \infty$ and hence can be interpreted as light tailed. Beta distributions (including the uniform) are among the most popular members of the corresponding domain of attraction. A simplification as for $\gamma > 0$ applies since in this case $g(x)/(x_+ - U(x)) \rightarrow -\gamma$.

With these alternatives we arrive at the so-called three types theorem. The determination of the limits is due to Fisher and Tippet [6] while that of the domains of attraction was derived by Gnedenko [7].

Fisher–Tippett–Gnedenko Theorem The extreme value distributions are exactly those that agree to within type with one of the following ($\alpha > 0$)

1. Pareto–Fréchet-type ($\alpha > 0$) or type II:

$$\Phi_\alpha(x) = \begin{cases} 0 & \text{if } x \leq 0 \\ e^{-x^{-\alpha}} & \text{if } x \geq 0 \end{cases} \quad (5)$$

Moreover $F \in \mathcal{D}(\Phi_\alpha)$ iff for $x \rightarrow \infty$

$$\frac{1 - F(\lambda x)}{1 - F(x)} \longrightarrow \lambda^{-\alpha}, \quad \forall \lambda > 0 \quad (6)$$

2. Gumbel-type or type I:

$$\Lambda(x) = e^{-e^{-x}}, \quad x \in \mathfrak{R} \quad (7)$$

Moreover $F \in \mathcal{D}(\Lambda)$ iff for some auxiliary function b

$$\frac{1 - F(x + tb(x))}{1 - F(x)} \rightarrow e^{-t} \quad (8)$$

3. Extremal Weibull-type ($\alpha > 0$) or type III:

$$\Psi_\alpha(x) = \begin{cases} e^{-|x|^\alpha} & \text{if } x \leq 0 \\ 1 & \text{if } x \geq 0 \end{cases} \quad (9)$$

Moreover $F \in \mathcal{D}(\Psi_\alpha)$ iff $x_+ < \infty$ and

$$\frac{1 - F(x_+ - \frac{1}{\lambda x})}{1 - F(x_+ - \frac{1}{x})} \rightarrow \lambda^{-\alpha}, \quad \forall \lambda > 0 \quad (10)$$

In reliability applications one often uses the *hazard function* that is defined by the ratio $r(x) := f(x)/(1 - F(x))$, where f is the density of F . For the three types there exist sufficient conditions in terms of this hazard function. We use the formulation of the Fisher–Tippett–Gnedenko theorem above.

von Mises Theorem Sufficient conditions for the extremal distributions are

1. for the Pareto–Fréchet-type: $x_+ = \infty$ and $x r(x) \rightarrow \alpha > 0$;
2. for the Gumbel-type: $r(x)$ is ultimately positive in the neighborhood of x_+ , is differentiable there and satisfies $r'(x) \rightarrow 0$;
3. for the Weibull-type: $x_+ < \infty$ and $(x_+ - x) r(x) \rightarrow \alpha > 0$.

The above results can be found in all treatments of extreme value analysis. We refer to Beirlant *et al.* [3], Coles [8], Embrechts *et al.* [4], Galambos [9], Leadbetter *et al.* [10], Reiss and Thomas [11], or Resnick

[12] where the reader can also find information on a number of statistical issues that are dealt with in the next section.

Statistical Aspects

The most important statistical questions related to extreme value theory are the **estimation** of the EVI γ , and the estimation of extreme **quantiles**. A further step would be to obtain confidence intervals for these quantities and to construct hypotheses tests. We briefly deal with these problems referring the reader to the aforementioned treatises for more information.

Estimation of the EVI

Two different approaches are available: either one looks at sample values that overshoot a certain threshold or one only uses a number of the largest order statistics.

- In the first case, the *peaks-over-threshold (POT) method*, a threshold u is chosen. The domain of attraction, formulated in terms of the distribution F shows that F is well approximated by the parameterized distribution

$$P\left\{\frac{X-u}{\sigma} > y | X > u\right\} \sim 1 - \left(1 + \frac{\gamma y}{\sigma}\right)^{-1/\gamma} \quad (11)$$

for all y values for which the right-hand side is feasible. The distribution on the right-hand side has been called the *generalized Pareto distribution*. The estimation of the parameter γ can be done by maximum-likelihood methods as shown by Smith [13, 14]. Alternative methods are the kernel methods of Csörgő [15], the method of probability-weighted moments of Hosking *et al.* [16], or the elemental percentile method of Castillo and Hadi [17].

- Other authors have advocated a nonparametric approach where γ is estimated using the order statistics of the sample.
 - If γ is known to be positive, then many estimation procedures exist. The most classical estimator

$$H_{k,n} := \frac{1}{k} \sum_{i=1}^k \{\log X_{n-i+1,n} - \log X_{n-k,n}\} \quad (12)$$

has been proposed by Hill [18] and is called *Hill's estimator*. This estimator and some of its kernel versions treated by Csörgő *et al.* [15] are fully covered in Beirlant *et al.* [3].

- In the general case, the choice for appropriate estimators is harder. Possible candidates are
 - * the estimator proposed by Pickands [19]

$$\frac{1}{\log 2} \log \frac{X_{n-k+1,n} - X_{n-2k+1,n}}{X_{n-2k+1,n} - X_{n-4k+1,n}} \quad (13)$$

or the refined versions by Drees [20] or Segers [21];

- * the *moment estimator* introduced by Dekkers *et al.* [22]

$$H_{k,n} + 1 - \frac{1}{2} \left(1 - \frac{(H_{k,n})^2}{H_{k,n}^{(2)}}\right)^{-1} \quad (14)$$

where in turn $H_{k,n}^{(m)} := \frac{1}{k} \sum_{i=1}^k \{\log X_{n-i+1,n} - \log X_{n-k,n}\}^m$, $m > 1$;

- * or a third alternative introduced in Beirlant *et al.* [23, 24]

$$\frac{1}{k} \sum_{i=1}^k \{\log UH_{i,n} - \log UH_{k+1,n}\} \quad (15)$$

where $UH_{i,n} = X_{n-i,n}H_{i,n}$, and $H_{i,n}$ is the Hill estimator.

In the POT method the choice of u is crucial while in the above estimators the choice of the quantity k is critical. In general, k should be small enough to avoid large **bias**, simultaneously k should be large enough to control the variance. One possibility, fully covered in Beirlant *et al.* [25,3], is to minimize a nonparametric estimator of the **mean squared error**. Other choices with their supporting arguments are presented in Danielsson *et al.* [26], Drees and Kaufmann [27], and Gomes and Oliveira [28]. In all cases k should tend to ∞ together with n but in such a way that $k/n \rightarrow 0$.

Estimation Of Extreme Quantiles

In practical situations one often likes to estimate the quantity x when the probability $p = P(X > x)$ has been fixed. In terms of the quantile function one then wants an estimate for the p th quantile, or $x = q_p := Q(1 - p)$. If we use our nonparametric approach, then we should use a random threshold like for example, the $(k + 1)$ -largest observation $X_{n-k,n}$.

From equation (11) we infer that the tail of F is well approximated by the right side of the equation. Given that we have an estimator $\hat{\gamma}$ of γ and one for $\hat{\sigma}$ of σ , q_p is estimated by

$$\hat{q}_p = X_{n-k,n} + \hat{\sigma} h_{\hat{\gamma}} \left(\frac{k}{np} \right) \quad (16)$$

where h_p is found in equation (3). This approach to estimate extreme quantiles and tail probabilities was first worked out in detail by Smith [14] and Dekkers and de Haan [29].

In the special case where $\gamma > 0$, we know from the Fisher–Tippett–Gnedenko result that

$$\lim_{t \rightarrow \infty} \frac{(1 - F(t))}{(1 - F(t))} = y^{-1/\gamma} \quad (17)$$

for every $y > 1$. Using the same thinking as above we find an alternative estimator

$$\hat{q}_p^+ = X_{n-k,n} \left(\frac{k}{np} \right)^{\hat{\gamma}} \quad (18)$$

a tail estimator for Pareto-type tails initiated in Weissman [30].

In **time series** analysis, in particular, in hydrology, an alternative way of looking at quantiles is very popular. The *return period* of an extremal event is defined by $T(x) = \{P(X > x)\}^{-1}$. It gives an indication of the time that elapses between two repetitions of events that themselves have a small probability of happening.

Note that in case $\gamma < 0$, one can let $p \downarrow 0$ to get an estimator for x_+ , the mostly unknown right-hand point of the distribution. More specifically, $\hat{x}_+ = \hat{\sigma}/|\hat{\gamma}|$.

Of course, one can also use the POT approach to get estimators for the quantiles and x_+ . For a full treatment, see Beirlant *et al.* [3].

Other Questions

- Without further assumptions, the construction of **confidence intervals** and the *reduction of the bias* in the above estimations are hardly possible. Indeed, in order to gain information about the asymptotic behavior of certain estimators, one needs *second-order properties* of the tail quantile function U or equivalently of F . We follow de Haan and Stadtmüller

[31] but other authors use different approaches. In addition to the existence of the EVI γ and the auxiliary function g , one assumes a second ultimately positive auxiliary function g_2 with $g_2(x) \rightarrow 0$ when $x \rightarrow x_+$, such that the limit

$$\lim_{x \rightarrow x_+} \frac{1}{g_2(x)} \left\{ \frac{U(ux) - U(x)}{g(x)} - h_{\gamma}(u) \right\} =: k(u) \quad (19)$$

exists and is neither identically zero nor a multiple of $h_{\gamma}(u)$. Quite generally one can then show that $g_2(u) = c h_p$ for a quantity $\rho \leq 0$ and a nonzero constant c . This second-order parameter appears in the detailed study of the bias and the variances of the classical estimators for the EVI γ . We refer to Beirlant *et al.* [3] for more explicit results and references.

- The area of **hypothesis testing** has hardly been explored. Among the few explicit results we mention the following. For an overview of what is available, see Fraga Alves and Neves [32].
 - Assume that $F \in \mathcal{C}_{\gamma}(g)$, where g is known. Then one can test the hypothesis $H_0(\gamma = 0)$ against the alternative $H_1(\gamma \neq 0)$. For two such approaches, see Hosking [33] and Segers and Teugels [34].
 - If F is strictly Pareto, that is, $1 - F(x) = cx^{-\alpha}$ then a hypothesis of the type $H(\alpha = \alpha_0)$ can be reduced to a similar test for the parameter of an exponential distribution. For explicit results, see Teugels and Van Assche [35] and its references.

Discussion of Available Results

As explained, the main goal of extreme value statistics is to estimate crucial parameters that are strongly influenced by the extremes in the sample. In particular we mentioned the EVI, high quantiles and endpoints of distributions. But overall, the assumptions made in the previous section are not always satisfied.

Classical Case

In cases where the classical theory does not apply immediately, the investigator has a number of possibilities to adapt the analysis. We mention a few.

Transformations. Sometimes a simple rewriting of the sample may already help to get a better view

of the right tail of the underlying distribution. If $\{X_i, 1 \leq i \leq n\}$ is a sample from X , then it might be advantageous to use a continuous function T to transform the data $\{X_i^* := T(X_i), 1 \leq i \leq n\}$ in such a way that the extremes of this new set have nicer statistical properties. For instance, the classical **Box–Cox transformation** $T(x) = (x^\sigma - 1)/\sigma$, ($\sigma \in \mathbb{R}$) often serves as an important example. If T is strictly increasing, then we can write for all $y > 1$:

$$\begin{aligned} P(T(X) > x) &= P(X > T^{-1}(x)) \\ &= \frac{1}{y} \iff x = T(U(y)) \quad (20) \end{aligned}$$

This means that the tail quantile function of $T(X)$ is given by the composition $T \circ U$. In Teugels and Vanroelen [36], the effect of a Box–Cox transformation on the data is fully investigated and illustrated with concrete examples. Of course, other transformations are possible as well.

Minima. Within a reliability context it is often more important to investigate the *minimum* of a sample rather than the maximum. This happens for example, in breakdown problems where the weakest link is responsible for the failure of the system. By the simple transformation $W_i = -X_i$, $1 \leq i \leq n$ on a sample, $\min_{1 \leq i \leq n} W_i = -\max_{1 \leq i \leq n} X_i$ and the classical results can be applied.

Regression Models. In classical statistics, a lot of attention has gone into methods to detect the role played by covariates on the common statistical procedures. This theme is far less popular in extreme value theory where estimations are rephrased in their conditional alternatives. Following Beirlant *et al.* [3], we can group the existing methods into four categories.

- The *method of block maxima* where the entire data set is cut in independent pieces and one or more parameters in the extremal distributions are expressed in terms of covariates.
- For the logarithms of the *spacings* between successive order statistics the classical theory has constructed exponential regression models based on second-order properties. These *quantile methods* can be extended to include **covariate** information.

- The *POT method* can be extended to allow the parameters in the generalized Pareto distribution to depend on covariates.
- A number of *nonparametric estimation procedures* such as maximum penalized likelihood or local polynomial maximum likelihood can be combined with extreme values.

Bayesian Analysis. In extreme value statistics, decisions often have to be taken on the basis of a small number of events. Moreover, such decisions are commonly of a prospective nature. For example, questions like 100-year return times are common in environmental contexts. Furthermore, prediction fits well in a Bayesian framework. Finally, some of the classical estimation approaches suffer from extra regularity conditions that need not be satisfied. For example, maximum-likelihood procedures sometimes fail if the EVI is negative. It is therefore advisable to help the investigator with expert opinions, an attitude that is typical for Bayesian statistics. Furthermore, Bayesian alternatives might help when classical methods fail.

In spite of the fact that some important attempts have been made, Bayesian Analysis for extremes is still in its infancy. Thanks to the availability of **Markov chain Monte Carlo** techniques some of the earlier computational problems can be circumvented. For a more or less full description of existing procedures and a number of case studies, see Beirlant *et al.* [3] or Coles [8] where further references are given.

Dropping the i.i.d. Assumption

In many applications the usual assumptions of independence and/or identical distribution are not realistic. Dropping the assumption of independence or/and of identical distribution leads to new problems.

- It has been shown in Leadbetter *et al.* [10] that the extremal laws are rather *robust* in the sense that under mild regularity conditions, the same laws appear for the case of weakly dependent random variables. See Deo [37] and Hsing [38] for more recent approaches for the statistical determination of an analog of the EVI.
- The incorporation of a further *time* or/and *spatial component* would of course make the above more applicable to practical data. In [39] Smith treats spatial models. Tail inference based on

high-level crossings of stationary sequences is treated by Leadbetter [40]. Time series models with extremal marginals are covered in Hall and Tajvidi [41].

- Rare events and extremes for *regenerative processes* are treated by Asmussen [42] and by Falk *et al.* [43]. For extremes in *Markov chains*, consult Bortot and Coles [44] and Bortot and Tawn [45].

Multivariate Extremes

For a number of years, extensions of univariate results to the situation of *multivariate extremes* have been developed. Take $\{(X_i, Y_i), 1 \leq i \leq n\}$ a sample from a bivariate distribution. It should be clear that even the concept of a multivariate extreme can be interpreted in a variety of ways. Still, the most common interpretation is $(X_{n,n}, Y_{n,n})$, the coordinate maximum. The basic limit theory has been started by de Haan and Resnick [46].

In multivariate extreme value theory one first makes transformations of the marginal distributions by applying a one-dimensional analysis on them. What remains can then be formalized in a *dependence function* or *copula*. Because of the high complexity of the latter, researchers fall back on parametric or semiparametric assumptions. Among the many proposals we mention a few.

- In [47], Tawn makes a number of proposals for modeling this dependence function. Nonparametric and parametric estimators of the parameters in the dependence function are discussed.
- For other representations, based on Pickands' approach, see Falk *et al.* [43].
- Hall and Tajvidi [48] suggest the use of a mixture of parametric and nonparametric methods to construct prediction regions in bivariate extreme value problems. The nonparametric part of the technique is used to estimate the dependence function (or copula) while the parametric part is employed to estimate the marginal distributions.
- Cai and Li [49] use a dependence function that is based on a multivariate phase-type distribution.

The problem of estimating multivariate *exceedance probabilities* was initiated in de Haan [50]. Also, in the multivariate setting one can break away from the i.i.d. case. For example, in [51] de Haan and Huang treat the problem of estimating extreme quantile

curves in two-dimensional distributions. Mikosch [52] models extremely large values in multivariate time series.

Intercalibration Studies

Introduction

The Biological Effects Quality Assurance in Monitoring Programmes (BEQUALM) self-funded scheme was initiated to develop quality standards for a range of biological effects techniques and to monitor compliance of laboratories generating data from these techniques for national and international monitoring programs (e.g. OSPAR, Oslo and Paris Commissions) and also for regulatory purposes. This self-funded scheme has now been running for 2 years. The “whole organism” component of this scheme deals with aquatic ecotoxicological techniques, which determine the inherent toxicity of a sample of water or sediment, using a variety of aquatic organisms. Each year, the lead laboratory (Cefas) organizes a program of intercalibration exercises for each of the methods included in the scheme. In this paper, the results from an intercalibration using a 48-h acute test with *Daphnia magna* (water flea) are described.

Each intercalibration exercise is divided into two parts. In the first (termed the *unknown test*), laboratories were given an unspecified concentration of a reference chemical (zinc sulphate), which they were asked to dilute by a given factor and estimate the toxicity of the substance in terms of the percentage mortality. In the second part (termed the *reference test*), a predetermined dilution series of the reference chemical was prepared by each laboratory from a provided stock and mortality at each concentration measured. From these mortalities, the medial lethal concentration (EC_{50}) was estimated for each laboratory.

In the *Daphnia* tests that are described here, six laboratories took part in the unknown tests and seven in the reference tests. However, repeat tests using different operators – particularly from laboratory 11 – meant that effectively eleven sets of results were received for both the unknown and the reference tests. To maintain confidentiality of a laboratory's results, each was randomly allocated a number.

All computing was done using the package S-plus [1].

Statistical Methods

The Unknown Test

All but one laboratory deployed a test design involving four replicates of five *Daphnia* for both controls and the unknown concentration. One laboratory used 2 replicates of 10 *Daphnia*. The controls were not used in the analysis but were used as a criterion for validity of the test, i.e. to ensure that the test animals were healthy and the environmental conditions of the test were correct. If more than 10% of the control animals died then the unknown sample data was rejected. For the *Daphnia* data described here, this did not happen for any laboratory.

The important summary statistics for the unknown samples are the mean and the standard deviation of the mortality rate estimated by each laboratory. From these, simple **confidence intervals** for the laboratory's mean mortality rate can be obtained.

The next step is to establish whether any of the results from the laboratories are inconsistent – i.e. determine if there are problems with any laboratory's procedures. The difficulty with doing this is that a **benchmark** by which to judge the performance of the laboratories needs to be established. Ideally, this should be independent of the current data. In this case it was possible to use data from the previous year, since the same concentration of the unknown sample was used. A *consensus mean* was thus calculated based on the laboratories that were deemed compliant in the 2004/2005 testing [2]. However, if the level of the unknown sample had changed – as it will in future years – the consensus mean would need to be based upon the current year's data. In such cases, some form of robust estimator that is less influenced by **outliers** would be preferable. This, therefore, means that the results from extreme laboratory results do not unduly influence the level of the consensus mean (if they did, it would mean that such a laboratory would be less likely to be deemed noncompliant). The preferred choice of such an estimator – which is used for the second stage of the study – is the robust M-estimator with bi-square down-weighting of **residuals** [1].

However the consensus mean is calculated, the assumption is effectively made that the majority of the laboratories are “correct” and that laboratories that deviate from this consensus are noncompliant. Clearly, this is where some nonstatistical ecotoxicological detective work can be used to establish why

2 Intercalibration Studies

laboratories are noncompliant or, indeed, whether they are correct and all of the others are wrong!

A common statistical technique to assess whether the results of a laboratory are consistent with the consensus mean is through the use of *Z*-scores [3]. This assumes the null hypothesis that each laboratory mean ($\bar{p}$) has a **Normal distribution** with mean equal to the consensus mean (p) and variance given by $\text{Var}(p) = p(1 - p)/N$, where N is the total number of animals over all replicates for the unknown sample ($N = 20$ for the *Daphnia* data). If the modulus of

$$Z = \frac{\bar{p} - p}{\sqrt{\text{var}(p)}} \quad (1)$$

is larger than, say, the 97.5% quantile of a standard Normal distribution (tolerance limit), then the laboratory is deemed to be noncompliant. A slight technical improvement on this can be obtained, as has been done here, by using exact tolerance limits based on Binomial distributions rather than approximations to the Normal distribution.

While the use of *Z*-score methods allows us to investigate inconsistencies of a laboratory's mean estimate of mortality, it does not allow for consideration of the variation over repeat tests. One way to do this is to use a, so-called, *P*-score defined as

$$P = \frac{s_p}{\sqrt{\text{Var}(p)}} \quad (2)$$

where s_p is the standard deviation over replicates for a particular laboratory. Effectively, a comparison is being made of the ratio of the observed laboratory standard deviation to its binomial theoretical value assuming that the mortality rate is the same for all replicates and that mortality is independent. A *P*-score much greater than unity suggests that there is additional variation in the experimental procedure. Exact tolerance limits were obtained by simulating data based on the binomial distribution with a probability of death of the consensus mean and calculating the *P*-score each time.

The Reference Test

Here, each laboratory tests across a series of contaminant concentrations and mortality is calculated at each level. The Majority of the laboratories used four replicates of five *Daphnia* for each of the contaminant concentrations stipulated to be tested by the lead

laboratory: 0, 0.1, 0.32, 1.0, 3.2, and 10 mg l⁻¹ zinc. However, laboratory 8 used additional intermediate concentration levels at 0.56 and 1.8 (which presumably was the concentration range this laboratory routinely used when conducting *Daphnia* tests), laboratory 9 used only 2 replicates but with 10 *Daphnia* in each replicate, and laboratory 12 used 6 replicates at concentration level 0. These different designs are all acceptable within current international guidelines (e.g. OECD [4]; ISO [5]).

The EC₅₀ is defined as the concentration at which the mortality is 50%. If mortality does not reach 50% for any laboratory, then it is excluded from the analysis and is deemed clearly noncompliant. The EC₅₀ was estimated by modeling the mortality proportion (m) as a logistic **generalized linear model** with $\log(\text{concentration} + 0.001)$ as the explanatory variable [6] and with binomial errors. Thus

$$m = \frac{\exp(\beta_0 + \beta_1 \log \text{Conc})}{1 + \exp(\beta_0 + \beta_1 \log \text{Conc})} \quad (3)$$

The EC₅₀ is estimated by finding the concentration for which $m = 0.5$ in equation (3). This gives $\widehat{EC}_{50} = e^{-\widehat{\beta}_0/\widehat{\beta}_1}$, where $\widehat{\beta}_0$ and $\widehat{\beta}_1$ are the maximum-likelihood estimates.

Confidence intervals for the EC₅₀ estimates could not be obtained empirically because the majority of laboratories carried out the procedure only once. One possibility would have been to construct **bootstrap** confidence intervals for the EC₅₀ based on **resampling** the data [7]. However, a profile-likelihood method was chosen to construct 95% profile-likelihood confidence intervals [6]. The method is more fully described in Appendix A.

Similar diagnostics were calculated for the values of EC₅₀ in terms of their mean value and their precision, as was done for the unknown test above. However, because repeat replicates were not available, the procedure required modification. The consensus EC₅₀ (denoted as EC₅₀^c) was estimated from a logistic model fitted to the pooled 2004/2005 data – but excluding noncompliant stations. A form of “*Z*-score” indicating the difference between the consensus mean and that from each laboratory was calculated as follows:

$$Z = \text{EC}_{50}^c - \text{EC}_{50} \quad (4)$$

The 95% tolerance limits for the EC₅₀ *Z*-scores were estimated by simulation (see Appendix B). As

Figure 1 Unknown concentration plots for *Daphnia*. (a) Mean mortality estimates and confidence intervals; (b) Z-scores and 95% tolerance limits; (c) P-scores and 95% tolerance limits

previously stated, those laboratories where the Z-score is contained within the tolerance limits could be considered to have complied.

To assess the variance of the EC_{50} estimate obtained by each laboratory an approximate method based on a truncated Taylor series expansion was used. The ratio of this variance was compared with the empirical EC_{50} estimates from the simulations used above to obtain the tolerance limits for the EC_{50} Z-scores (further details are given in Appendix C). As done for the unknown test, an evaluation is being made of how consistent the variance of the EC_{50} from an individual laboratory is with the variance obtained under the underlying binomial model for mortality and the consensus EC_{50} .

Results

Unknown Test. The consensus mean of 0.58 was calculated from the 2004/2005 data, excluding the results of two laboratories where the mean mortality was exceptionally high or low.

The mean mortality rates and concentrations (Figure 1(a)) suggest that laboratories 3 and 12 have

low mean estimates. This is confirmed by the Z-scores plot (Figure 1(b)) which shows that laboratories 3 and 12 are noncompliant in terms of their mean estimate. The P-scores plot (Figure 1(c)) suggests that laboratories 2a and 11a have variances that are too high. However, given that all of the other results for laboratory 11 are compliant in terms of mean and variance, then, overall, this laboratory seems to have performed quite well. The variances for laboratories 3 and 12 are on the border of the lower limit. Coupled with their rejections from the Z-score tests, there seems to be some indication that there are problems with method performance.

Reference Test. Figure 2 shows the EC_{50} estimates for each laboratory together with their fitted logistic model. Laboratories 11(a) and (b) have a steep gradient from 0 to 100% deaths and the deaths for laboratory 12 do not get very high even for the highest concentration (fitting in with the low deaths for the unknown concentration for this laboratory).

Figure 3 shows the EC_{50} estimates and profile-likelihood confidence intervals. Laboratories 2b and 12 are the furthest from the consensus EC_{50} , which

Figure 2 EC_{50} models and estimates for each laboratory

was calculated as 1.35 from the 2004/2005 data, excluding outlying results from two laboratories.

Figure 4(a) shows the EC_{50} Z-scores plot. Laboratories 2b, 11c, 11d, and 12 are all noncompliant. Figure 4(b) shows the P -scores plot. Laboratories 2b and 12 have excessively high variability, whereas 8, 11a, and 11b are all marginally too low. Overall, laboratory 12 demonstrates particularly poor performance in the test.

Discussion

We have described the procedures that are used to analyze some of the biological effects data in the BEQUALM scheme. The aim of this quality assurance scheme is to evaluate and monitor the ability of laboratories to competently perform ecotoxicity tests, the data from which are being submitted to national and international environmental monitoring programs and also for regulatory purposes (e.g. chemical registration). There are several benefits in taking part in such proficiency testing schemes. For example, satisfactory performance allows a laboratory to

provide additional confidence in the quality of their results to laboratory clients; unsatisfactory performance indicates a problem with the methodology at a laboratory, whether that be inexperience with the test and/or operator, problems with equipment **calibration**, and so on, and allows remedial actions to be initiated.

The self-funded scheme has been running for 2 years. Both practical and statistical methods have been modified as a result of the first year. It is expected that modifications will continue to be made into the second year. There are a number of improvements that could be made. For example, confirmation is needed that the sample sizes (five *Daphnia*, four replicates) used in the unknown tests are sufficient to ensure that important biological departures by laboratories can be picked up in the Z-score and P -score tests. Having said that, given that a number of laboratories are currently picked out as noncompliant by these tests, the sample sizes do seem to be reasonably adequate. It would be very beneficial if laboratories performed replicate tests so that empirical estimates of the variance of EC_{50} estimates could

Figure 3 EC_{50} estimates and profile-likelihood confidence intervals: (a) all laboratories; (b) excluding laboratory 12

Figure 4 Z-scores and P-scores for the EC_{50} estimates. The values for laboratory 12 are not plotted because they are so extreme

be obtained. This would remove the need for some of the model-based and simulation techniques described in this article.

Many of the methods described in this article

are based on computer-intensive model fitting and simulation. These methods are not, of course, an end in themselves. The intention has always been to use these to provide evidence for potential deficiencies in

the procedures carried out by laboratories and thus discriminate between acceptable and unacceptable data for inclusion in large monitoring/regulatory programs.

Appendices

Appendix A – EC_{50} Profile-Likelihood Confidence Interval

To construct a profile-likelihood 95% confidence interval we reparameterized the logistic model as follows:

$$\begin{aligned}\log \text{it}(p) &= \beta_0 + \beta_1 \log \text{Conc} \\ &= \beta_1 (\log \text{Conc} - \log EC_{50}) \\ &= \beta_1 X\end{aligned}\quad (5)$$

To construct the profile likelihood, we vary the estimate of the EC_{50} around its original maximum-likelihood estimate $\hat{EC}_{50}$ and construct the 95% profile-likelihood confidence interval to include values of EC_{50} such that $(\text{Dev}(\hat{EC}_{50}) - \text{Dev}_0) \leq 3.84$, where Dev_0 is minus twice the log-likelihood at the maximum-likelihood estimator and $\text{Dev}(\hat{EC}_{50})$ is minus twice the log-likelihood estimator for model (5) above.

Appendix B – Tolerance Limits for EC_{50} Z-scores

The 95% tolerance limits for the Z-scores were estimated by simulation. At each concentration, we simulated binomial data with number of trials equal to the number used by the laboratory – with the probability of death taken from the value from the fitted model used in calculating the consensus mean from the 2005 data. From these simulated data, we calculated the EC_{50} estimate. We repeated this process 1000 times and the approximate 95% tolerance limits for the Z-scores are given by the 25th and the 975th ordered values.

Appendix C – Comparing the Variances of the EC_{50} Estimates

The variance of the EC_{50} estimate for a particular laboratory is obtained using an approximate method

based on the parameter estimates from the logistic model. This is derived as follows:

$$\log \hat{EC}_{50} = -\frac{\beta_0}{\beta_1} \quad (6)$$

Using a standard truncated Taylor series expansion we get

$$\begin{aligned}\text{Var}(\log \hat{EC}_{50}) &= \frac{1}{\beta_1^2} \left\{ \text{Var}(\hat{\beta}_0) \right. \\ &\quad + 2 \log \hat{EC}_{50} \text{Cov}(\hat{\beta}_0, \hat{\beta}_1) \\ &\quad \left. + (\log \hat{EC}_{50})^2 \text{Var}(\hat{\beta}_1) \right\}\end{aligned}\quad (7)$$

Thus, using a similar Taylor series truncation we obtain

$$\text{Var}(\hat{EC}_{50}) = \hat{EC}_{50}^2 \text{Var}(\log \hat{EC}_{50}) \quad (8)$$

The variances and the covariances of the parameter estimates come from the fitted logistic model for each laboratory.

Define an EC_{50} P-score by

$$P = \frac{\text{Var}(\hat{EC}_{50})}{\text{Var}(\hat{EC}_{50\text{sim}})} \quad (9)$$

where $\text{Var}(\hat{EC}_{50\text{sim}})$ is the variance of the 1000 EC_{50} s calculated from the simulations described in Appendix B.

The tolerance limits come from the 25th and 975th largest values of equation (9) when the approximate variance $\text{Var}(\hat{EC}_{50})$ is calculated from each of the simulations.

Fisheries Stock Assessment

Fishing is an economically and socially important activity with around 90 million tonnes of wild fish caught each year [1]. Fisheries policy tries to balance potentially conflicting management drivers for sustainability and maintenance of ecosystem biodiversity with socioeconomic drivers of profit and employment at a variety of geographic scales. Stock assessment's role is to provide the best possible technical support to this process [2], estimating current and possible future fishery states, and the effects of management decisions. Stock is used to define a part of a fish or shellfish population. Stocks are usually identified by location, e.g., "Bay of Biscay sole", and generally treated as self-sustaining and distinct from other stocks.

The assessment process involves collecting data direct from the fishery and from "fishery-independent" sources, such as research vessel surveys. To turn these data into quantitative estimates of stock size and composition, a wide range of mathematical models is available [3]. These range from simple line fitting to complex models that integrate multiple data sources. Cotter *et al.* [4] note that stock assessments should be explicable to stakeholders; allow data sets to be weighted in relation to the independent information they contribute; use sampling data or estimates only once, and make due allowance for dependence among data. There is an art to a good assessment: to ensure that modeling assumptions are reasonable, that outputs translate sensibly to the observed situation, and information outside the mathematical model is considered, as "no fishery model can be completely trusted to capture biological reality" [5].

Data Collection

Representative **data collection** is needed to enable accurate and precise stock assessments. This falls into two categories: data referring to the fishery (catch, effort) and those referring to stock biology (length, weight, age, etc.). Details of sampling strategies and techniques should be noted in standard operating

procedures (SOPs) to ensure consistency over time and between samplers.

Data on the amount of fishing effort and fish landed are collected in two ways: census or more commonly **survey sampling**. Sampling officers visit ports and record required details for a selection of vessels, while interviews, either face to face or via telephone, may be used to collect fishery information from recreational or artisanal fisheries. See Catch Statistics in [6] for more details. Avoiding or accounting for unreported landings is an important **data quality** issue for fisheries. **Quality control** can be aided by cross-checking logbook data recorded at sea, landing declarations, and sales receipts. Observation flights and satellite-based position monitoring on larger vessels also provide useful information on fishing locations.

As fishery-based data reflect fishing practices, economics, and technological improvements as well as stock biology, "fishery-independent" data collected using standardized methods plays a vital role in many assessments. This is most commonly from a trawl survey using a research or chartered fishing vessel (see Catch Statistics and Trawl Surveys [6]). Alternatively, acoustic surveys can be used to cover large volumes of water. These surveys use equipment that must be frequently calibrated with a reference target of known target strength, as it is affected by regional changes in water salinity and temperature (affecting sound speed and absorption) [7]. Other abundance **estimation** methods include aerial surveys to identify and quantify schools of fish, use of underwater cameras, and surveys which sample fish egg distributions, leading to fish population estimates based on the number of eggs [8].

A basic quality assurance matter in all these approaches is the correct identification of species. Visual identification of common and commercial species is generally near perfect in both commercial and fishery-independent approaches, but may be inconsistent for rare species or juveniles of related species without regular training and assessment. For acoustic surveys, converting acoustic readings to species densities can work well for single species aggregations and individual animals, while for complex multispecies aggregations, there have been considerable developments in hardware and classification algorithms but automated species identification remains the goal. The ability of scientists to correctly

2 Fisheries Stock Assessment

identify the species of fish eggs has been considerably enhanced by DNA-based methods [9].

Biological information is often collected alongside fishing data, using stratified **sampling schemes**. The simplest biological data to collect are fish lengths, grouped to form length distributions. The box tally system (Figure 1) improves the quality of data recording to paper as it is clearer and provides less chance for error than the more usual tally gate. Direct-to-computer length recording, using devices such as electronic calipers and electronic data-capture fish-measuring boards, also improves quality. The boards have a ruled scale with a bar code at each length. When an infrared pen is swiped across the bar code, translation software on a computer recognizes the measurement and enters it into a database. Quality control checks on individual fish length and weight are incorporated into fisheries data entry systems using historical records of maximum lengths and published relationships between length and weight [10].

For many fish species, age can be estimated from hard body structures such as scales, spines, and otoliths (calcareous structures near the back of the skull). As fish grow, marks are deposited through which fish age can be estimated, similar to counting rings in a tree trunk (Figure 2). The marks must be validated, confirming that the start and frequency of growth patterns matches the expectations for fish of known age [11]. Common interpretation of patterns must be ensured. With a sample of known ages, the age interpretation by individual scientists can be assessed graphically with an age-**bias** plot (known age against estimated age) and statistically tested for bias through aging error matrices and matched-pair tests. As known age samples are not regularly available, samples independently aged by a number of scientists can be compared, and measures of bias and precision calculated from the most common age ([12]; www.efan.no).

Measuring a fish is much cheaper than aging it. Therefore, often a subsample of measured fish are aged, and observed age-length keys (proportions at age by length) or modeling [13] used to estimate

Figure 1 Box tally recording symbols

Figure 2 Cod otolith cross section showing annual growth zones. Actual width, 12.5 mm, tip to tip

the age composition of the total landings needed for many stock assessments. Recent developments incorporate otolith weight as additional information in this process [14].

As with age, fish maturity is assessed visually. By inspecting the fish's gonads, scientists can tell if the fish has the ability to spawn and its stage in the annual spawning cycle, based upon standard texts e.g., [15]. Microanalysis of gonads is usually recommended for precise assessment of the developmental stage, rather than macroanalysis, but is more time consuming. Sample exchanges to ensure consistency are problematic as they involve soft tissue. Instead, exchanges of digital photographs and scientific workshops can be used.

Fish tagging studies use simple marker tags and more recently electronic tags, which provide a detailed **time series** of observations. These studies provide information on fish migration, help define stocks, and provide growth and survival data. They can also provide the basis for mark-recapture methods to estimate population size (e.g., [16]), particularly for species such as salmon that have part of their life cycle in freshwater. Double tagging of fish can investigate the effects of tagging on mortality and growth, or estimate rates of tag shedding.

Stock Assessment Methods

There is a wide and expanding variety of stock assessment methods, the most appropriate of which will depend upon the nature of the fishery, the presence

and quality of biological and fishery data, and the skills available [17, 18]. Most operational assessments are for single stocks, although multispecies models [19] are used for scenario modeling and meta-analysis is used to study patterns across many stocks. There is also growing emphasis on assessing the effects of fishing on ecosystems as a whole.

Single stock methods develop from those using only catch and effort data, by including biological processes such as recruitment (the amount of juvenile fish entering the fishery) and by increasing the biological structure with length, age, or stage-based models. Spatial structure of the stock may also be included. Many of the methods have now been developed in a state–space framework to include observation and process error. Bayesian estimation methods are increasingly common, allowing integrated assessment of uncertainty in assessment outputs [20].

Time series of catch and effort data allow biomass dynamic models (also called *surplus production methods*) to be used. These simply model population growth as a function of total biomass. Delay-difference models extend this by including age-structured dynamics and a time lag between spawning and recruitment. Depletion methods based on a closed system estimate stock size by extrapolating decreases in catch as cumulative effort increases. Catch survey analysis extends this to an open system and has similarities to mark-recapture analysis. With detailed information on the contribution of individual cohorts to the catch (through sampling programs and age readings), catch-at-age methods can estimate the historical status of a population. By tracking catch-at-age back through time, they estimate the population that must have been present in the water to produce the observed catch. Cohort or virtual population analysis (VPA)-based methods assume catch data are exact, whereas other catch-at-age methods allow observation and process errors by making other modeling assumptions. For species that are difficult to age, length-based models can be used [3, 21]. These generally either split the length frequency data into separate cohorts based on an assumed growth model and length-at-age distributions or model the transition from one size group to the next.

With many of the methods, catch per unit effort (CPUE) is used as a measure of abundance either directly or as additional “tuning” information for **calibration**. An assumption that CPUE is proportional to abundance should be carefully checked, particularly

for fisheries-dependent data, otherwise it may cause bias. Often, **generalized linear models** and their extensions are used to improve the index of abundance [22].

After estimating current status, management considerations require short-term forecasts of catch and biomass against management objectives. These forecasts require an estimate of current population size, the likely exploitation pattern, estimates of the size of recruiting year classes, and assumptions of future overall levels of fishing mortality. The population is projected forward to identify which levels of fishing may achieve desired future stock status. These projections can be highly dependent upon the assumptions made. As a result, the longer the projection, the more uncertain the output, as projections are unlikely to be able to predict shifts in the environment or the impact of multispecies interactions. When communicating these forecasts and stock assessment results, an element of probability can be used, e.g. the estimated probability of an unwanted event occurring or cumulative probability distributions of meeting a required biological level [23].

Assessing the Assessment

Once complete, stock assessments are peer reviewed before findings are presented to managers and policy makers. Statistical methods are available to estimate uncertainty in the results [24], while reporting of uncertainty is an integral part of Bayesian approaches. The performance of stock assessments can be determined against reference data sets, although these may not reflect all the issues encountered in practice. Various diagnostics, sensitivity checks, and repeat runs to determine the robustness of assessment estimates to different weightings of data sets can be examined [3].

Stock assessments are only a part of the management regime in operation. Hence their evaluation needs to encompass whether the data and assessment methods available for management are sufficient to meet management objectives, and whether they, and the management plan itself, are robust to both the statistical uncertainty and the incomplete knowledge on factors such as stock identification and abundance, stock dynamics, and the impacts of environmental variability and trends [25]. The performance of assessments and management should therefore be simulation tested using approaches comparable

to those developed by the International Whaling Commission [26]. Where plans are inadequately precautionary, targets, constraints, the management procedure, or assessment can be modified and reevaluated. Alternatively, critical uncertainties in the process can be identified and further research initiated to reduce them before initiation of the plan.

DAVID L. MAXWELL AND GRAHAM M.
PILLING

Sampling Sediments in the Marine Environment

Introduction

The marine environment covers more than 70% of the earth's surface and is a fundamental ecosystem which influences our weather patterns and from which we derive mineral resources and food. The seas are also a major transport system and provide significant leisure opportunities. However, over the years, we have deposited a considerable quantity of waste products into our seas and continue to use them in this context, although to a lessening extent. In addition, our marine environment is often the final location for hazardous substances brought to the seas by either rivers or through atmospheric deposition. As such, there is a clear need to understand our marine ecosystem. This requires that we make measurements – physical, chemical, and biological. In recent years, governments have become increasingly aware of the importance of our marine waters and require that we improve our understanding of how they are changing and what is causing such changes. The UK Government outlined its proposal for the marine environment in 2002 when it published *Safe-guarding Our Seas – A Strategy for the Conservation and Sustainable Development of Our Marine Environment* [1]. This presented the vision of clean, healthy, safe, productive, and biologically diverse oceans and seas and was followed, in 2005, by the devolved administration in Scotland presenting a supporting vision [2]. Also in 2005, the United Kingdom published *Charting Progress – An Integrated Assessment of the State of UK Seas* [3]. This brought together UK marine monitoring data, which was then used to describe and evaluate the current state of UK seas and also present some trends. Assessing “where we are” and “where we are going” is a feature of marine science which has been reiterated in the developing European Marine Strategy Directive [4]. However, to be able to fulfill the vision of clean, healthy, safe, productive, and biologically diverse seas and oceans, a definition of “clean” and of “safe” is required. In addition, there is a need to detect temporal trends, to be able to describe areas of the seabed, and to compare one area of the seabed with another and describe any difference such as concentrations of persistent

organic pollutants (POPs). There is also a requirement to be able to comment on whether changes in practices and procedures have resulted in improvements to our marine environment. Ultimately, this requires the collection and analysis of samples of water, sediment, and biota. Collecting sediment from the seabed is a costly process due to the need for a ship. In addition, it can be time consuming since sampling can be hindered by bad weather. Collecting a sediment sample from the seabed that is under 130 m of water requires specialized samplers, but to date we are, in effect, sampling blind since we cannot see the seabed being sampled nor how characteristic the sample is of the surrounding sediment. Constraints on sampling require that optimal sampling regimes, with a sound statistical basis, are developed. At the **Fisheries Research Services Marine Laboratory**, hazardous substances in marine sediments have been determined for some years (e.g. [5–8]). During this time, statistical tools have been used to develop sampling protocols, which have allowed differences in the concentration of hazardous substances between locations to be detected with a known statistical **power**, as well as optimize the number of samples that are required to provide data that is representative of the geographical area of interest.

Fjordic Sea Lochs

Fjordic sea lochs are characteristic features of the west coast of Scotland. They typically exhibit restricted circulation and accumulate fine-grained sediment with high organic carbon content. As such there is the potential to accumulate organic pollutants, especially those with an octanol water partition coefficient ($\text{Log } K_{ow}$) greater than 4. This includes polycyclic aromatic hydrocarbons (PAHs, e.g., pyrene, $\text{Log } K_{ow} 5.85$; benzo[a]pyrene, $\text{Log } K_{ow} 6.35$), chlorinated biphenyls (CBs, e.g., CB22, $\text{Log } K_{ow} 5.67$; CB153, $\text{Log } K_{ow} 6.92$) and polybrominated diphenyl ethers (e.g., 2,2',4-tribromodiphenyl ether (BDE 17), $\text{Log } K_{ow} 5.74$; 2,2',3,4,4',5',6-heptabromodiphenyl ether (BDE 183), $\text{Log } K_{ow} 8.27$). A study was undertaken to investigate the PAH composition of sediments from such sea lochs. This came immediately after a study into the PAH content of sediments from voes (small bays or narrow creeks) around the Shetland Islands impacted by the *Braer* oil spill of 1993. As part of this initial study, a sampling protocol was

2 Sampling Sediments in the Marine Environment

designed on the basis of previous data to ensure a 90% statistical power for detecting a 65% difference in total PAH concentrations between reference voes and those within the UK Food and Environment Protection Act 1985 (FEPA) Exclusion Zone set up following the incident [9]. The sampling protocol involved firstly generating 36 random numbers between 0 and 15. The vessel sampled the first station and then moved at 4 knots over a predetermined track. Samples were collected at the time intervals, in minutes, taken from the random number table; a 0-min time difference resulted in a duplicate sample being taken. This resulted in pseudorandom generated points. The 36 samples from each voe were later pooled into six pools of six using random selection. Each pooled sample consisted of aliquots (25 ± 1 g) from six individual samples and from this the various aliquots for the determination of particle size, total organic carbon (TOC), moisture, and hydrocarbon composition and concentration were taken. Although it was possible to draw conclusions from the resulting data using a combination of multivariate and regression techniques [10], the pooling of samples was shown to introduce considerable variation in the data. Consequently, when undertaking the more extensive survey of voes and coastal areas around the Shetland and Orkney Islands [11] and sea lochs on the west coast of Scotland [12], a similar sampling procedure was followed, but on this occasion only 14 samples were collected across each loch. However, all 14 were subject to individual analysis. Furthermore, the random number table that was generated was limited to numbers between 0 and 10. Again this sampling procedure was chosen based on previous data to ensure a 90% statistical power for detecting a 65% difference in total PAH concentration in the top 2 cm of the sediment, between different voes and sea lochs. Such a process allowed a detailed analysis of the hydrocarbons in sediments from both the voes and coastal areas around the northern isles and the west coast sea lochs. Plotting the mean log total PAH concentration (normalized for TOC) at each site, with 95% confidence limits on the mean, against the corresponding mean log TOC, showed clearly that there were significant differences between the different sea lochs and voes. These could be explained by consideration of anthropogenic inputs and thus the sampling regime was deemed to have been successful. In the case of the data from the west coast sea lochs, applying principal component analysis (PCA) to the median parent

and alkylated concentration (normalized to TOC), in each PAH group, expressed as proportions of the total median concentration, it was possible to characterize the lochs on the basis of the PAHs present and, ultimately, to come to conclusions about probable sources of these contaminants.

Open Sea Areas Associated with Offshore Oil and Gas Exploration and Production

Open sea areas represent a slightly different challenge since circulation is not restricted in the way it is within a sea loch. This is also, to some extent, the case for more open coastal locations. Historically, sediments in open sea areas have been sampled using a systematic grid approach in which several transects across an area are sampled at regular intervals. This is how the Fladen Ground, a potentially accumulative area of the North Sea which is also an area of intense oil production activity, has been surveyed [13]. Although such an approach provides maximum spatial coverage of an area for a given number of samples, is a relatively simple design to implement, provides regularly spaced or timed samples which provide for spatial and temporal correlations to be calculated, and can be implemented with little or no prior information about the site, such a design may not be as efficient as other designs if some prior information is available which can be used in the design. In addition, a grid design copes less well with missing stations (e.g., stations not collected in any year due to bad weather or because a new production platform has been constructed since the last survey). In an attempt to provide an adequate assessment of the spatial distribution of hydrocarbons in the Fladen Ground, the area was sampled using a stratified random sampling design. This allows a much simpler statistical analysis to be done. A description of the analysis can be found in [14]. In this case, the Fladen Ground was partitioned into 16 equal zones. Samples were selected by random number generation in each zone, the number of samples per zone being proportional to the far field (defined as areas more than 5 km away from multiple oil wells or 2 km from single oil wells) within each zone (Figure 1). Although used on this occasion, proportional allocation is not the only way of assigning the number of samples to a zone. An alternative is optimal allocation. This process

Figure 1 The 16 zones and the location of the stratified random sampling sites (black dots) in the far field areas (defined as areas more than 5 km away from multiple oil wells or 2 km from single oil wells) of the Fladen Ground, North Sea. Gray circles are near field areas (big circles are multiple oil wells and small circles are single wells)

allocates more samples to be taken from zones with higher variability in concentration between samples within a zone. Prior knowledge of the variability in the measured parameters is required. Ultimately, this method allocates more samples to zones with high variability and thereby maximizes the precision of the estimates of mean concentration for the whole far field area across the sampling area, given a fixed total **sample size**.

On the basis of proportional allocation, sediment samples were collected from the Fladen Ground by Day Grab from the FRV *Scotia* and analyzed for TOC, particle size, fluorescence, and hydrocarbons [15]. The mean total PAH concentration was calculated for each zone and this was then used to estimate the mean value over the whole far field ($\bar{y}_{st}$) using the equation:

$$\bar{y}_{st} = \frac{1}{A} \sum_{h=1}^L A_h \bar{y}_h \quad (1)$$

where A is the overall far field area, $\bar{y}_h$ is the zone mean value in zone h , A_h is the far field area in zone h and L is the total number of zones. The **standard error** for $\bar{y}_{st}$ can also be calculated. In this

particular survey, the mean PAH concentration within each of the 16 zones ranged from 53.9 ng g^{-1} dry weight to 206.6 ng g^{-1} dry weight. The mean over the whole far field was estimated to be 108.2 ng g^{-1} dry weight with a standard error for the mean over the whole far field area of 2.7 ng g^{-1} dry weight [15]. Differences in PAH concentrations between zones were also investigated using analysis of variance (**ANOVA**) and this highlighted significant differences between geographically grouped zones. Thus, this particular sampling technique provided an assessment of the spatial distribution of hydrocarbons across the Fladen Ground.

Coastal Sea Areas

The coastal zone receives direct and indirect inputs of hazardous substances. In general, estuarine and coastal areas are more highly contaminated than off-shore locations. The UK coastal zone is monitored under the UK Clean Seas Environmental Monitoring Programme (CSEMP) of the UK Marine Monitoring and Assessment Strategy, until recently known as the *UK National Marine Monitoring Programme*. This

4 Sampling Sediments in the Marine Environment

program includes the determination of the concentrations of hazardous substance in marine sediments and of any temporal trends in the concentrations of these compounds. The focus of the program has moved from repeated sampling at fixed stations to using sampling designs that are more immediately applicable to larger sea areas. The implied increase in the number of samples requiring collection and analysis has the potential to greatly increase the overall cost of the program and thus alternative strategies have been developed. Using both the Firth of Clyde and the Firth of Forth as test areas, a composite random sampling design was compared with the more traditional simple random sampling design. Composite sampling involves the physical combination of a number of homogenized samples to form a set of new (composite) samples on which the analyses are then performed. In this case, 25 sediment samples were collected by Day Grab from the FRV *Clupea* in the Firth of Clyde and the Firth of Forth (Figure 2) using a simple random sampling regime; the locations for the individual samples were selected using a random number generator. Five composite samples were prepared from the 25 samples collected using the simple random sampling design, by combining equal weights

of sediment from 5 of the individual samples. The five groupings of five samples were done on a random basis. ANOVA and multiple comparison tests at a **significance level** of 5% were used to detect significant differences among the means of % Total organic carbon (TOC), particle size analysis (PSA), PAH concentrations, and *n*-alkane concentrations. Spearman's rank **correlation** was used to determine nonparametric correlations among the parameters measured.

There was no significant difference between the mean concentration of PAHs from the 25 initial samples and the mean for the 5 composite samples for either the Firth of Clyde or the Firth of Forth. Indeed, for all parameters measured, there were no significant differences between the mean values of the composite random sampling and of the simple random sampling ($p < 0.05$; ANOVA) for both the Firth of Clyde and the Firth of Forth sediments.

The different sources of PAHs can be distinguished using specific PAH ratios. When this was done for the 25 individual sediments from both the Firth of Clyde and the Firth of Forth, a clear separation between the two locations was evident (Figure 3) with the geographical samples showing distinct clusters. When the process was repeated for the five

Figure 2 Map showing the Firth of Forth on the east of Scotland and the sampling area from which 25 samples were collected at random. The 25 samples were randomly grouped into five groups of five and composite samples prepared based on the grouping. All 25 samples were analyzed together with the five composite samples and the data compared

Figure 3 Fluoranthene/pyrene (Fl/Py) ratio *versus* the phenanthrene/anthracene (P/A) ratio for sediments from both the Firth of Clyde and the Firth of Forth collected using a simple random sampling scheme (a) and the composite random sampling scheme (b)

composite samples, even tighter clusters were evident (Figure 3). It was interesting to note that for some determinants, the compositing process reduced the variance between samples to such a degree that the batch-to-batch variance of the analytical methods used became an important part of the residual variance in the field data. Thus the composite random sampling design provided better representation and better precision of an estimated mean than the simple random sampling design and at less cost.

Conclusion

The use of simple statistical approaches can contribute significantly to the development of sampling regimes, which reduce the variance in the data, enable larger sea areas to be described, and detect differences in the concentrations of hazardous substances between sea lochs with a defined statistical power. Such sampling regimes are already being introduced into marine **monitoring programs** around the United Kingdom.

Healthcare Performance Reports

Introduction

Reporting healthcare performance goes back at least to the pioneering work in the United States in 1754, when the Pennsylvania Hospital released tables of **health outcomes** tabulated by diagnostic groups [1]; and Florence Nightingale in England in 1860s, who presented analyses of hospital mortality rates [2]. Some information is relatively straightforward, such as waiting times and cleanliness; but assessing other dimensions of quality of care is typically problematic because health services are characterized by “heterogeneity, complexity, and uncertainty, and hence most performance indicators are ‘tin openers’ rather than ‘dials’ they do not give answers but prompt investigation and inquiry, and by themselves provide an incomplete and inaccurate picture” [3]. Iezzoni [4] points out that issues raised in the debate following Nightingale’s publication of hospital mortality rates echo those cited frequently about contemporary efforts at measuring provider performance, and include: risk adjustment; the need to examine mortality 30 days after admission rather than in-hospital deaths; and concerns over **data quality**, providers avoiding high-risk patients because of fears of public exposure, and the public’s ability to understand this information.

From the 1990s, technological advances in computing and web sites have resulted in an explosion in reporting of various kinds of healthcare performance. This has highlighted inadequacies and together with evidence of systems failures [5, 6] has further fuelled the demand for, and supply of, information on healthcare performance. There have been ambitious and controversial international comparisons of systems of healthcare [7, 8], assessments of countries’ own systems [9–14]. There is intense and polarized debate over the pros and cons of publication of performance data with different camps describing this as essential, desirable, inevitable, and potentially dangerous [15]. This article is about the impacts of healthcare performance reports within a country, which have been variously described as “report cards”, “consumer reports”, “public performance reports”, “provider/practice profiles”, “score cards”, “quality

assessment reports”, and “league tables” [16]; and confidential reports to individual clinicians as part of an audit process.

This article outlines issues raised by measuring performance, the models of impacts of information on healthcare performance, evidence of impacts, and concludes by discussing statistical implications.

Models of Impacts of Information on Healthcare Performance

To understand how reporting healthcare performance has an impact, we need a model of the links between the supply of this information and its impact on those who provide healthcare. Marshall *et al.* [15, p. 40] pointed out the lack of a commonly embraced rationale for the public release of performance data, which was believed to serve a wide variety of purposes and audiences. They identified three different models for professionals, public accountability, and markets which relate to three approaches [15, pp. 74–75]:

- **The “soft” approach**

In this model, clinicians are keen to improve their performance but hampered by a lack of comparative information, so a system is designed to provide information for **benchmarking** to enable those who want to improve to learn from the best. This approach is about quality improvement, focuses on success, and is voluntary.

- **The “hard” approach**

In this model the focus is on accountability and a requirement to meet minimum standards. This approach is compulsory and about quality assurance.

- **The market approach**

There are two models of the market approach because payments for healthcare are typically made not by patients, who are the consumers, but by third party payers (insurers or governments). These models are either corporate or consumers’ choices of health plans and corporate or patients’ choices of providers.

This article considers the impacts of reporting healthcare performance on four different groups: third party payers (either corporately or by consumers), patients, physicians, and providers. Reporting may also impact on the public perception of providers and inform and be part of policies for the regulation and management of systems of healthcare, in which

2 Healthcare Performance Reports

the role of the media is crucial. But if we are to understand the impact of reporting on healthcare performance, then it must be observed in these four groups: the other impacts are means to those ends.

Impacts

Third Party Payers

A problem for third party payers in the corporate model of the market approach is that for acute hospital care there is enormous heterogeneity in the scope of these services and only limited information for some services. In the United States, these payers were not always aware of available information: on clinical outcomes, consumer satisfaction data, and Health Plan Employer Data and Information Set (HEDIS) reports, that include performance measures of cancer, heart disease, smoking, asthma, and diabetes and a standardized survey of consumers' experiences. And those that were aware of this information found that it did not help them make decisions [16, 17]. Hence their early interest in this information soon waned and they focused on costs or gross indicators of quality through accreditation rather than detailed comparative information [16]. Consumers in choosing between health plans in the United States experienced further complications and difficulties: with lack of understanding of basic differences between types of insurance or how managed care plans could influence quality of care [18–21]. In the United Kingdom, the evidence is that District Health Authorities, the dominant third party payers, made little use of comparative information for contracting, but information on waiting times was used effectively by general practitioners (GPs), who had opted for their practices to become payers in the form of GP fundholders [17, 22–24]. The comparative effectiveness of GP fundholders to use simple information, illustrates that even if larger corporate payers had more adequate information on quality, they would face large transaction costs in using this for contractual purposes: it would no longer make sense to contract *en bloc* with providers: it would be necessary to go down to the level of clinical teams. The attraction of the market model of patient choice is that this promises a way of sending detailed signals at the level of clinical teams.

Patients

Reporting information to patients may be seen as part of the models that underlie the hard and the market approach. Both models assume that patients are aware of, can access, and understand this information; and the market model assumes they can use it to make choices [25].

Publication of surgical mortality rates for cardiac surgery in England [26] followed the landmark case of failure of self-regulation by the medical profession to take corrective action over high-mortality rates following pediatric cardiac surgery at the Bristol Royal Infirmary [27]. The Kennedy Report into the Bristol case observed that “little if any information was available to the parents or to the public. Such information that was given to parents was often partial, confusing, and unclear” [27, p. 3] and hence argued that “continued secrecy and anonymity, is no longer a real option”. The report in recommending that audit data be published recognized that these data are complex and hard to understand; may mislead the public, who might draw unwarranted conclusions; and may result in healthcare professionals being unfairly criticized [27, p. 398]. The report called for a new compact between the community and its hospitals in which the public must accept that the price of information is a considered and responsible reaction to it [27, p. 398]. This is different from the market approach as what is being advocated here is highly specific information relevant to patients, or, in this case, their relatives. But after that recommendation was made, when mortality rates of pediatric cardiac surgery at different centers were published [28], these were criticized as misleading and have been subsequently disputed [29].

The market model of patient choice requires designing a system in which providers' incomes depend on the numbers of patients they treat and assumes that choices made using information on quality of care will offer signals in a market which will drive providers to react. In this, model patients require timely specific information on the performance of the clinicians who supply diagnosis and treatment of their conditions. They thus encounter one of the problems of third party payers: that information is in the form of “tin openers” and coverage is partial, and this problem is exacerbated by patients' interest in timeliness. Second, a basic tenet of economics is that the consumers are skilled buyers of goods

and services that they buy repeatedly, so patients with chronic conditions can become expert patients and skilled users of the services that are available; but a patient with an acute condition will be in a very different position. The starting point of health economics is the asymmetry of information between such a patient and provider, which means that property rights over consumption are not exercised solely by the patient who relies on a provider to make a diagnosis, and the patient may from then on feel that choices are circumscribed. Such patients are often anxious and want to make a decision quickly: making choices over treatment for breast cancer is, e.g., rather different from choosing a used car. This would be difficult enough if perfect information were available, the information that is typically available is difficult to interpret, incomplete, partial, and out of date.

Hence we would expect patients to have problems in understanding and using publicly reported information on healthcare performance in either the market model or for the purposes of public accountability. And that is exactly what the evidence from the United States shows [16, 25]: when this information is published only a minority are aware of it, of those most do not understand it (including whether high or low rates of an indicator reflect good performance), trust it, or use it (with problems with timely access, and lack of genuine choice); and evaluations of later developments that addressed many of these potential barriers failed to demonstrate significant or sustained public interest. Keogh *et al.* [26] summarized findings from the publication of outcomes from cardiac surgery to conclude that what patients really want in the United Kingdom “is an operation in a hospital close to home and as soon as possible”. Furthermore, recent focus group data indicated antagonism from some members to public reporting in the accountability model, as they saw this as a punitive tool used by politicians to punish hardworking professionals [16].

Physicians

A crucial distinction in examining reporting information for clinicians is between the “hard” and “soft” approach, whether this is intended for quality improvement or assurance, which is in turn related to the issue of publication. Evidence shows that physicians were more aware than patients, of information,

which appears to have been directed at patients as consumers, but physicians too made little use of it in making referrals and distrusted and, in some cases, attempted to discredit the data [16, 24, 29]. There are concerns that publication of surgical mortality rates results in a defensive response by surgeons in which they refuse to operate on high-risk patients [15]; and one effect of reporting annual risk-adjusted mortality rates of coronary artery bypass graft (CABG) surgery in Pennsylvania was that over half the cardiologists reported increased difficulty in finding surgeons willing to perform CABG surgery in severely ill patients who required it, and over half the cardiac surgeons reported that they were less willing to operate on such patients [30].

The soft approach seeks to organize collection and publication of data in ways that enable clinicians to learn how to improve. Examples include the Northern New England Cardiovascular Disease Study Group [31], and national clinical audits in the United Kingdom, for example, for stroke [32] and myocardial infarction [33]. The Northern New England Cardiovascular Disease Study Group included feedback of outcome data, training in continuous quality improvement techniques, and site visits to other medical centers and the main outcome was a statistically significant reduction by nearly a quarter in the hospital mortality rate. In 1995, the key factors that were identified as contributing to the group’s success included: strong clinical leadership, regionally and at each institution; confidentiality of data, which were analyzed and returned in a timely fashion; and an organized forum for discussion [34].

Providers

Marshall *et al.* [16] pointed to a growing body of evidence to show that providers are the most sensitive of the four groups we have identified here to the publication of information. Despite the fact that providers’ common initial public reaction to reports of poor performance is to dispute their validity, in private they use the published information to focus on the quality of the data and care they provide. We give six important examples, of which all but one appear to have had an impact.

- Annual reporting of data on risk-adjusted mortality following CABG surgery by hospital and surgeon in New York state was the first

such program in the United States, beginning in 1989, and is now the most long lived. Chassin [35] observes that, between 1989 and 1992 risk-adjusted mortality fell by over 40% statewide in New York; which had, by 1992 the lowest risk-adjusted mortality rate of any state in the nation, and the most rapid rate of decline of any state with below-average mortality. He points out that these improvements happened because individual hospitals and cardiac surgery programs used the data to make specific changes in the way they provided care to CABG patients. Neither market forces nor managed care companies had an impact and patients did not avoid high-mortality hospitals nor seek out those with low mortality. As mentioned above, however, one reservation about the observed benefits of public reporting of surgical mortality rates is that, in private, cardiac surgeons turn away the sickest and most severely ill patients [25].

- Scotland's Clinical Resource and Audit Group (CRAG) [36] pioneered in Europe, in 1994, the publication of annual Reports of clinical outcome indicators for use by the public and doctors. CRAG's reports aimed to provide a benchmarking service for clinical staff by publishing comparative clinical outcome indicators across Scotland. Performance management was seen as a matter for local action: there were no external national pressures to act on CRAG's indicators other than publication. The main conclusions of two evaluations [36, pp. 223–229, 37] were that in Scottish trusts these indicators were rarely used to inform internal quality improvement or used externally to identify best practice with the reasons being: the information was regarded as out of date and lacking credibility, because of problems over the quality of the data and the lack of an adjustment for casemix; there was low awareness, because of little attention from the media and limited dissemination within each provider; the results were difficult to interpret, had limited coverage and were at too high a level of aggregation.
- From 1995, the Veterans Administration (VA) in the United States introduced **reengineering** to improve quality of care: routine performance measurements for high-priority conditions and performance contracts held managers accountable for meeting improvement goals. Data gathering

and monitoring were performed by an independent agency. Performance data were made public and were widely distributed within the VA, among key stakeholders such as veterans' service organizations, and among members of Congress [38].

- Hibbard *et al.* [39] undertook a controlled trial of the effects of reporting information on quality of care in 2001 between three sets of hospitals in Wisconsin: for the public-report set this information was published; the private-report set were supplied information privately (but this was not published), the control set received no report. The information included two summary indices of adverse events (deaths and complications) occurring within the broad categories of surgery and nonsurgery, and indices in three individual clinical areas. Hospitals were rated as better than expected, as expected, or worse than expected. The public-report hospitals were significantly more negative than the other two groups about the public report: its validity, value for quality improvement, and appropriateness for use by the public; but their efforts to improve quality were significantly greater than in hospitals given only private reports or provided with no information. None of the hospitals saw such information as having an impact on their market share (or "one like it" in the case of the private- and no-report hospitals), but the public-report hospitals saw this as having an impact on their public image.
- In England, from 2001 to 2005, annual performance ratings were published for NHS trusts in England [40–42]. This process gave each trust a rating from zero to three stars. Trusts that failed against a small number of key targets (dominated by waiting times) were at risk of being zero rated and their chief executives at risk of losing their job; trusts that performed well achieved three stars and were eligible for benefits from "earned autonomy". This system resulted in two kinds of outcomes: dramatic reductions in long waiting times in England, in line with the targets, which was not observed in the other countries of the United Kingdom; and various kinds of gaming, which included poor performance in domains where performance was not measured, what has been described as "hitting the target and missing the point", and exploiting ambiguity in reporting of data or fabrication in what was reported.

Statistical Implications

The survey of the various means of reporting information on healthcare performance suggests that this needs to be targeted at providers and be credible and timely; and also there ought to be widespread awareness of the results. This final section considers the statistical implications of translating data into information in these ways: the attraction and difficulties of producing individual indicators from measures of outcome and process, presentation of results including aggregation.

Outcome measures are of intrinsic interest and public appeal, and can reflect all aspects of care. But for an outcome to be a valid measure of quality, it must be closely related to a process of care that can be manipulated [43]. The data that are collected routinely on outcomes are typically limited to mortality and readmission. For hospital mortality at 30 days, indicators based on deaths in hospital may be inadequate and more reliable results are derived by linking data on hospital discharges to registry data on mortality [44]. Using outcomes to assess performance raises issues of risk rating: the data required may also not be collected routinely [45], and, even where data are available, there are serious methodological problems as it is not possible to predict with certainty which patients will recover from surgery. There have been particular problems with the high-risk population for CABG [46], which matters given marked variations in the proportion of individual surgeons' practices that are high risk. Using a single risk-adjusted number to summarize a surgeon's results runs the risk of lending "a level of spurious credibility to an analysis that does not take into account the impact of influences that are not patient related" [46]. One way of handling this problem, as the low-risk group was relatively homogeneous between surgeons, is to produce comparative analysis based on low-risk cases without the need for further risk adjustment [46]. This also has the advantage of making it clear that these indicators are "tin openers" [26]. Although measures of process lack the direct appeal of outcome measures, they can be more sensitive to differences in the quality of care [47], and are valid without the need for risk rating. There are issues over requirements for detailed clinical data that are currently found only in medical records [47], which may be more feasible with developments of electronic records [48].

Waiting times are important measures that are "gauges". There are statistical issues over how best to describe providers' performance. If, e.g., targets are in terms of the longest waiting times only, this obviously puts pressure on the providers with times that are above the target level to do better, but also creates a perverse incentive for those doing better than the target to allow their performance to deteriorate to the standard, and more generally to crowd performance towards the target [49]. Such effects can unintentionally penalize agents with exceptionally good performance but a few failures, while rewarding those with mediocre performance crowded near the target range.

Funnel plots that plot performance in terms of scale with error limits are based on sound statistical theory and are easy to understand [50] are a good way of presenting results for individual indicators. Aggregating performance of complex organizations into a single score is misleading as this fails to capture their complexity, and in the case of star ratings means it was difficult for a provider to understand why its performance changed [51] and league tables that simply rank organizational performance are easy to understand but unsound [52, 53]. What is required is developing ways of reporting data to give signals at a high level and organized to enable the investigation of those signals by drilling down.

Disease Mapping

Disease Mapping basics

Disease mapping is the analysis of epidemiological or public health data which is geo-referenced. Typically the data arises in two forms: either (a) the residential addresses of people affected by disease are known, or (b) counts of disease observed within arbitrary small areas such as census tracts, zip codes, or postcodes are available. The locational information is used in the analysis usually to make inferences about spatial health effects.

Often hypotheses of interest in disease mapping focus on whether the residential address of people affected by disease yields insight into the etiology of the disease or, in a public health application, whether adverse environmental health hazards exist locally within a region (as exemplified by local increases in disease risk). For example, in a study of the relationship between malaria and diabetes in Sardinia a strong negative relationship has been found. This relation had a spatial expression and the geographical distribution of malaria was important in generating explanatory models for the relation [1]. In public health practice it is of considerable importance to be able to assess whether localized areas that have larger than expected numbers of cases of disease have in common any underlying environmental cause. Here, spatial evidence of a link between cases and a source is fundamental in the analysis. Evidence such as a decline in risk with distance from the putative source of hazard or elevation of risk in a preferred direction is important in this regard (see e.g., Lawson *et al.* [2], Lawson [3, Chapter 7], and Elliott *et al.* [4]).

There are four main areas where statistical methods have seen development: *disease map reconstruction*, *disease clustering*, *ecological analysis*, and *disease map surveillance*. The term *disease mapping* is used in different contexts to either signify the group of methods that are applied to disease maps, or more specifically the **estimation** of relative risk from disease maps (*disease map reconstruction*). Hence there can be some confusion in the use of this term. It is appropriate to consider some common themes or issues, which arise in all areas of the subject.

Basic Definitions and Models

A fundamental feature of data available for analysis is that it is usually discrete (either in the form of a point process or counting process), and the cases of concern arise from within a local human population, which varies in spatial density and in susceptibility to the disease of interest. Hence any model or test procedure must make allowance for this background (nuisance) population effect. The background population effect can be allowed for in a variety of ways. For count data, it is commonplace to obtain expected rates for the disease of interest based on the age–sex structure of the local population, and some crude estimates of local relative risk are often computed from the ratio of observed to expected counts (e.g., standardized mortality ratios (SMR's) or standardized incidence ratios). For case event data, expected rates are not available at the resolution of the case locations and the use of the spatial distribution of a control disease has been advocated. In that case, the spatial variation in the case disease is compared to the spatial variation in the control disease. A major issue in this approach is the correct choice of control disease. It is important to choose a control that is matched to the age–sex structure of the case disease but is unaffected by the feature of interest. For example, in the analysis of cases around a putative health hazard, a control disease should not be affected by the health hazard. Counts of control disease cases could also be used instead of expected rates when analyzing count data. Figures 1 and 2 display case event and control data maps for a region of the United Kingdom for a fixed time period. Figure 3 displays a typical count data example.

Case Event Data

Case event locations often represent residential addresses of patients, and the patients are from a heterogeneous population that varies in both spatial density and susceptibility to disease. A heterogeneous **Poisson process** model is often assumed as a starting point for further analysis. The focus of interest for making inference regarding parameters describing excess risk lies in a relative risk function, which is included in the first-order intensity of the Poisson process.

It is possible that population or environmental heterogeneity may be unobserved in the data set.

2 Disease Mapping

Figure 1 Distribution of death certificate addresses of gastric and esophageal cancer in Arbroath, Scotland, UK (1966–1976)

This could be because either the population background hazard is not directly available or the disease displays a tendency to cluster (perhaps due to unmeasured covariates). The heterogeneity could

Figure 2 Control distribution: distribution of death certificate addresses for lower body cancers Arbroath, UK (1966–1976)

be spatially correlated, or it could lack **correlation**, in which case it could be regarded as a type of “overdispersion”. One can include such unobserved heterogeneity within the framework of conventional models as a random effect.

Figure 3 Distribution of counts of congenital deaths within the counties of South Carolina, USA 1990

Count Data

Considerable literature has developed concerning the analysis of count data in spatial analysis of disease (e.g., see reviews in [3–6]).

The usual model adopted for the analysis of region counts assumes that the counts are independent Poisson random variables with parameter 2_i in the i th region. This model may be extended to include unobserved heterogeneity between regions by introducing a prior distribution for the log relative risks ($\log 2_i$). Incorporation of such heterogeneity has become a common approach and the Besag, York, and Mollié (BYM) model is now a standard model. A full **Bayesian analysis** using this model is available on WinBUGS. A recent overview of Bayesian methods in disease mapping is found in [7].

ANDREW B. LAWSON

Disease Surveillance

Disease Surveillance Basics

Disease surveillance is the detection of aberrations in health or disease, usually as they arise. This definition stresses both the unusual nature of the disease event and the importance of temporal change in surveillance. How “unusual” an event or a sequence of events is, is of course an issue in the design of any surveillance system. The Centers for Disease Control (CDC) defines surveillance as:

the ongoing, systematic collection, analysis, and interpretation of health data essential to the planning, implementation, and evaluation of public health practice, closely integrated with the timely dissemination of these data to those who need to know. The final link of the surveillance chain is the application of these data to prevention and control. A surveillance system includes a functional capacity for **data collection**, analysis, and dissemination linked to public health programs [1].

This definition stresses the collection, analysis, and dissemination of data in a timely manner. Hence, it is a very broad definition that places an emphasis on public health needs. However it is possible to distinguish two basic types of surveillance that play different roles in public health activities.

First, *retrospective* surveillance concerns the collection of historical data on disease occurrence and its examination. The purpose of such analysis may be to inform decision makers as to temporal or spatial trends and other features of disease behavior. This form of surveillance is closely associated with classical epidemiological analysis, and differs mainly in its focus on public health needs.

Second, *prospective* surveillance is the on-line or active examination of disease data to discover changes in disease at or close to the time of occurrence. In this case, monitoring of disease occurrence is done “as data arrive” so that decisions can be made concerning outbreaks of disease. The importance of the latter form of surveillance has been heightened with the recent rise in terrorism and the potential threat to health from bioterrorism.

The release of toxic or highly infectious agents into a population would be of grave concern in this context and so it is now important that fast and

accurate surveillance of diseases be undertaken to detect changes as early as possible.

The design of disease surveillance systems must consider some of the following issues:

1. Early detection

It is important to detect changes in disease incidence as early as possible. For example, for certain infectious diseases it may take up to 7 days to receive laboratory confirmation of cases. However such a delay may be unacceptable if a serious event had occurred. Hence ways to speed up detection could be important.

2. Syndromic methods

The use of ancillary information to speed up detection of population health aberrations. A formal definition is given by Sosin [2]

...the public health term Syndromic Surveillance has been applied to systematic and ongoing collection, analysis and interpretation of data that precede diagnosis (e.g., laboratory test requests, emergency department chief complaint, ambulance response logs, prescription drug purchases, school or work absenteeism, as well as signs and symptoms recorded during acute care visits) and that can signal a sufficient probability of an outbreak to warrant public health investigation.

Hence, often, **covariate** information could be useful in helping to establish the character of an outbreak. Figure 1 displays the **time series** of pharmaceutical sales and gastrointestinal disease reporting for a Canadian example (see for further examples Lawson and Kleinman [3]).

3. Sensitivity and specificity of detection methods

The **calibration** of a surveillance system is very important in that false aberration alarms (false positives) could lead to unnecessary public alarm, while false aberration negatives could lead to health disasters. Farrington and Andrews [4] and Le Strat [5] provide more details on these issues.

4. Which disease and what to look for?

In retrospective surveillance, the disease is usually known and the features of interest are also known (e.g., trends). In prospective surveillance, particularly where bioterrorism may play a role, there could be little *a priori* knowledge of the disease and the

Figure 1 Battlefords Saskatchewan: Epidemic curve and time series of over-the-counter (OTC) pharmaceutical sales from January to May 2001

aberration to look for. Hence, detection systems must have the capability to deal with multiple diseases and possibly multiple forms of aberration. This is known as *multivariate-multifocus* surveillance. Because of the potentially huge database searching problem that results from this, *data mining* approaches have been adopted (see, e.g., Wong *et al.* [6] and Madigan [7]).

Aberration Types

1. Temporal

In temporal surveillance, a time series of events is available (usually either as counts of disease in intervals or as a point process of reporting or notification times). With time series of discrete counts,

the aberrations that might be of interest (suggesting “important” disease changes) are highlighted in Figure 2. In this figure, there are three main changes (A, B, C). The first aberration (A) is a sharp rise in risk (jump) or change point in level. The second aberration (B) that might be of interest is a cluster of risk (an increase then decrease in risk). This can only be detected retrospectively of course. The third aberration (C) is an overall process change where in addition to the change in the level of the process the variability is also increased or decreased.

When a point process of event times is observed, action may need to be taken whenever a new event arrives. Aberrations that are found in point processes can take the form of unusual aggregations of points (temporal clusters), sharp changes in rate of

Figure 2 Schematic features of changes/aberrations found in temporal surveillance

occurrence (jumps), and overall process change (as above).

2. Spatio-temporal

If a spatial domain (disease map) is to be monitored, then spatial and spatio-temporal aberrations must be considered. Spatial aberrations could consist of discontinuities in risk between regions (jumps in risk across region boundaries), spatial clusters of risk (localized aggregations of cases of disease), and long-range trend in risk.

When disease maps are monitored in time, *changes* in the above features might be of interest. The development of new clusters of (say) infectious disease in time might signal localized outbreaks, for example.

Multivariate Issues

In health surveillance systems designed for prospective surveillance, many of the above features would have to be detectable across a wide range of diseases. Not only would whole disease streams be monitored, but subsets of disease streams may also need to be examined. For example, for early detection of effects it may be important to monitor frail subsets (such as the old or young age groups), and correlations between subsets may be important to making detection decisions. In addition, if disease maps are to be monitored over time as well as time series, then the problem grows considerably. The *Biosense* system developed by CDC (www.cdc.gov/phn/component-initiatives/biosense/index.html) has a multivariate and mixed-stream (spatial and temporal) capacity.

Models

One of the current concerns about large-scale surveillance systems is the ability to correctly model the variation in disease and to properly calibrate sensitivity and specificity with such a multivariate and multifocused task. The application of Bayesian hierarchical modeling has been advocated for surveillance purposes and this may prove to be useful in its ability to deal with large-scale systems evolving in time in a natural way. For example, recursive Bayesian learning could be important. Clearly computational issues could be paramount here given the potentially multivariate nature of the problem, and the need to optimize computation is paramount. Sequential **Monte Carlo** methods have been proposed to speed up computation [8–10] and faster algorithms are also available [11].

ANDREW B. LAWSON

Healthcare Policy and Management of Stroke, Breast Cancer, and Mental Health

Introduction

Usually the main stated goal of healthcare policy makers and managers is to use available resources to achieve the greatest possible improvement to the health and well-being of the people they serve. Health is often a cumulative result of a variety of influences or services, either provided or not provided, by a variety of organizations over time. A healthcare system is one of many players. In addition to a direct role using its own resources, the healthcare system also has a role in acting as an advocate for health and as a partner with other organizations concerned with health. Any serious attempt at monitoring the achievement of stated health goals should reflect this more complex reality. This article attempts to show the kinds of monitoring questions that policy makers and managers are often faced with and the role of statistics in such monitoring. Statistics on **health outcomes** that are available within the National Health Service (NHS) in England for stroke, breast cancer, and mental health related services, on the basis of work undertaken by the National Center for Health Outcomes Development (NCHOD), are used to illustrate the issues raised. Gaps in existing data and their implications for policy making and management are discussed briefly. The generic issues raised and illustrated here should be applicable to other healthcare systems and other types of health problems. In a short article it is only possible to provide an overview of concepts, methods and issues. Further details on these are available in the *Clinical and Health Outcomes Knowledge Base* published by NCHOD [1].

Policy and Management Questions Concerning Health Services

Figure 1 is a population health overview for stroke related services, developed by NCHOD [1], as an illustrative way of drawing a variety of linked health

states and services together to provide a summary overview of policy and management issues. It shows further categorization of “health improvement” to reflect more specific aspects of outcome, i.e., success in:

- reducing the risk of developing high blood pressure (HBP) and stroke;
- reducing the level of HBP to prevent stroke;
- reducing adverse consequences of blood pressure treatment such as drug side effects;
- reducing adverse consequences (other than death) of lack of timely and appropriate health care, such as preventable strokes and their complications, pressure sores;
- restoring function and improving quality of life; and
- reducing premature deaths.

Similarly, the services needed to achieve such success are divided into more precise categories, i.e.,

- proactive services to avoid the risk of developing HBP;
- timely detection of risk and removal/reduction of existing risk to health;
- timely services to detect and treat HBP; and
- late services to minimize consequences of stroke.

This presentation helps to clarify and highlight what we are trying to achieve, covering positive aspects such as improved quality of life as well as negative aspects such as avoidable disease and ill health. It reflects aspects such as clinical signs and disease as well as those of more immediate concern to patients such as handicap and impact on quality of life. It shows how lack of action may lead to a chain of potentially avoidable consequences, from risk, to disease, complications of disease, poor quality of life, and premature death and shows the kinds of action that may alter these consequences for the better. It also shows feedback loops, for example, a patient developing a stroke being at risk of developing a further stroke and needing all the services for reduction of risk and treatment of HBP. It should be noted that presentation of data in the context of such a “health outcomes overview” describes mismatching outcomes at a point in time. The data on risk show risk to future health. The data on levels of disease and death show consequences of missed opportunities to reduce risk (if applicable) in the past.

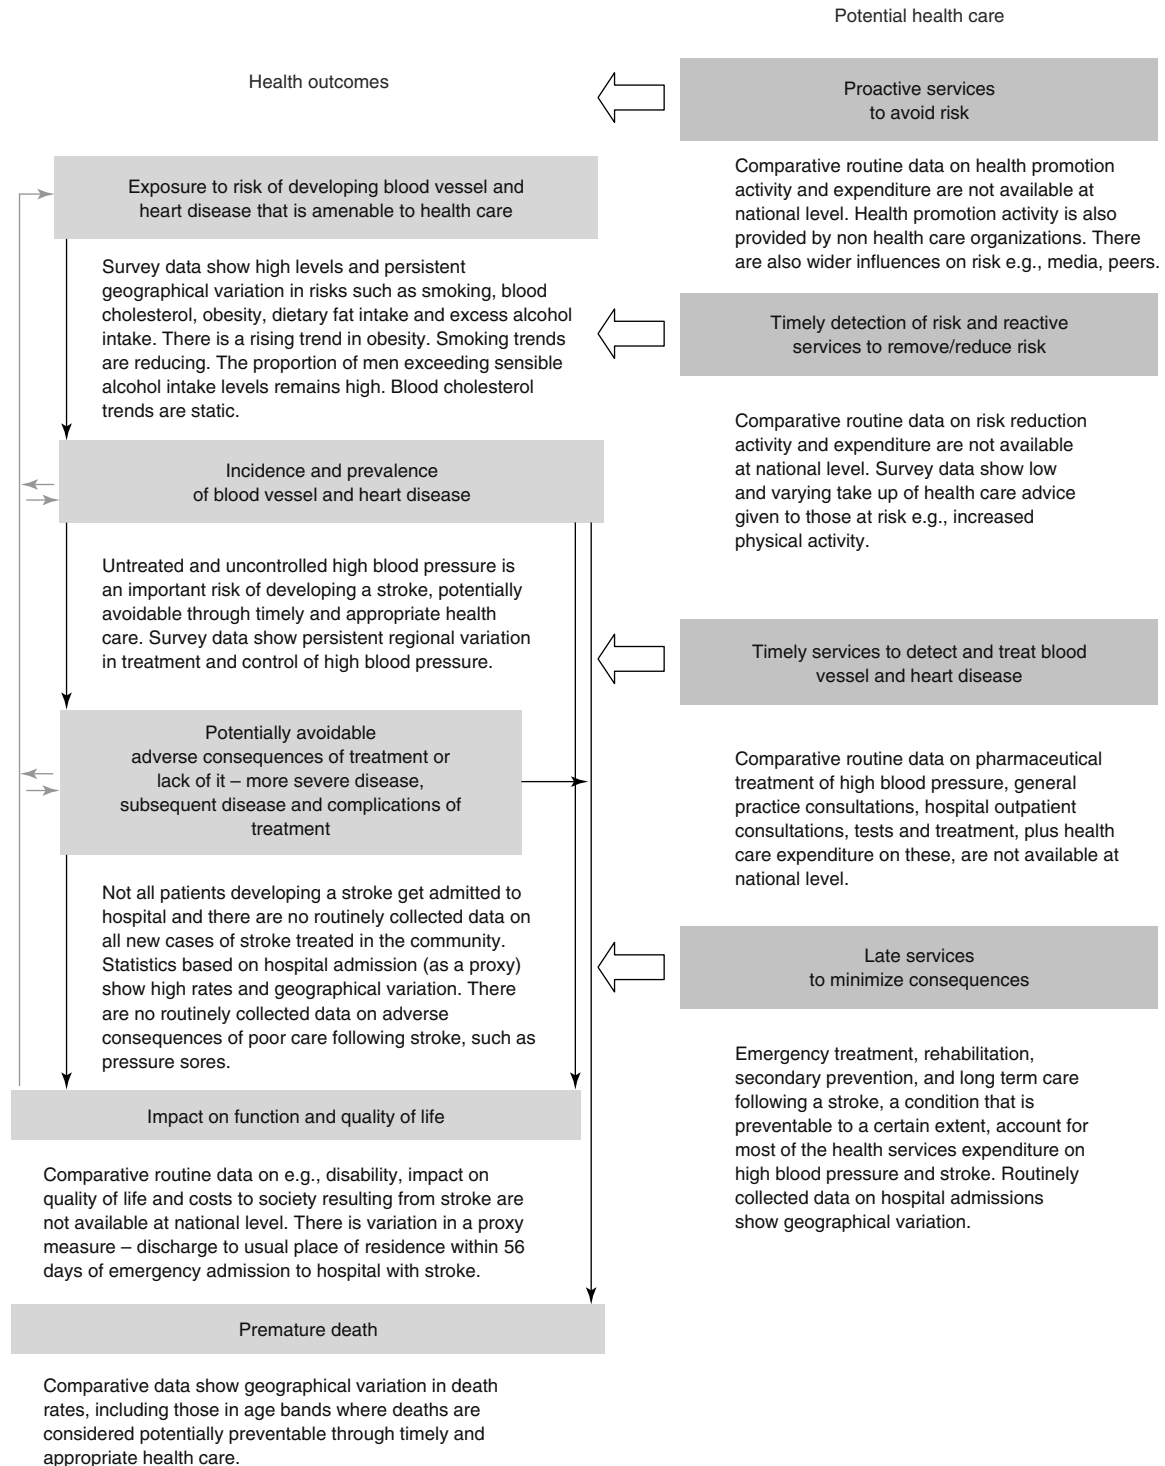

Figure 1 Overview of health care and outcomes: high blood pressure/stroke

It is also not possible to draw direct inferences on “attributable effects” of the services, as there may be different populations involved and a time lag between the services and the outcomes. However, such an approach does bring disparate but related items of information together in a meaningful way.

The same approach may be used to consider policy and management questions concerning breast cancer and mental health services. NCHOD’s Clinical and Health Outcomes Knowledge Base [1] contains health overviews with indicators for both conditions in its section on concepts and frameworks.

Statistics for Monitoring Achievements – Stroke

The greatest proportion of healthcare expenditure on HBP and stroke [2] is on stroke treatment, rehabilitation and long-term care, even though stroke is to a certain extent preventable through health service intervention. In assessing what is being achieved by healthcare, single indicators in isolation would present an incomplete picture of a complex reality.

Table 1 contains a set of indicators, drawn from NCHOD’s *Compendium of Clinical and Health Indicators* [3] that provide a more detailed insight as follows:

- A statistically significant rising trend in obesity. This implies an increasing future risk of HBP and stroke, and hence of future healthcare resource needs. Obesity is only partially amenable to health care.
- A statistically significant rising trend in levels of treated and controlled HBP (the single most important known preventive health service for stroke), although there is still plenty of room for improvement. In 2002, out of 10 653 adults of all ages with blood pressure measurements in the health survey for England (HSE), 25.1% had untreated HBP, and a further 8.4% had HBP that was treated but not controlled [4].
- A statistically significant falling trend in population levels of hospitalization for stroke. In the absence of suitable community based data, emergency hospital admissions may be used as a rough proxy for incidence, although not everyone with a stroke is admitted to hospital, and this will vary geographically. New guidelines on the development of dedicated stroke units were expected to

lead to an increase in hospital admission rates, so a falling trend may indicate falling incidence.

- A statistically significant rising trend in emergency readmissions after live discharge from hospital following treatment for stroke. A proportion of these readmissions may be due to potentially avoidable adverse events.
- A statistically significant falling trend in deaths after admission to hospital following a stroke.
- A statistically significant rising trend in timely discharge to usual place of residence. The timing is a proxy for completed treatment and rehabilitation, and a discharge to a place other than the usual place of residence may be indicative of an important life change and poor outcome.
- A statistically significant falling trend in population mortality from stroke. It is suggested that 70% of stroke mortality represents failure of secondary prevention and treatment by healthcare organizations, and 30% represents failure of primary prevention, some but not all of which is amenable to health care [5]. There is some overlap with the indicator on deaths after admission to the hospital.

These indicators provide a mixed picture. The NHS is improving on several fronts, but many of its resources are used for managing problems that are to some extent preventable. There is a concern about how stroke hospital activity (and its commensurate expenditure) should be used in the assessment of what is achieved. On the one hand it reflects services provided by a healthcare system when needed, but on the other, is a consequence of past failures of the healthcare system. This set of indicators also raises the issue of a time lag between resource use and its impact.

Variation in What is Achieved Through Stroke Services

Alongside reviewing national data and trends, policy makers and managers also need to review data at the level of geographic, administrative, or provider organizations. Variation in indicator values between such organizations may be either due to special local issues and circumstances or a reflection of inefficiency in the healthcare system. Table 1 shows variation between geographic administrative organizations in England (minimum and maximum values for each indicator

- (a) Financial year; FY.
- (b) Organizations: SHA = NHS Strategic Health Authorities, PCO = NHS Primary Care Organizations, LA = Local Authorities (local government) – boundaries as at April 2003.
- (c) Sources of data: HES = Hospital Episode Statistics, ONS = Deaths data from the Office for National Statistics, HSE = Health Survey for England, Continuous inpatient spells (CIPS) combine all contiguous episodes across all NHS hospitals for treatment, rehabilitation and care within the year of analysis for individual patients.
- (1) Directly age and sex standardized percent of adults (16+) who are obese (body mass index over 30) for 1998–2002, standardized using the England 2001 census noninstitutional adult population count (*Source*: HSE).
 - (2) Those on prescribed blood pressure drugs with a blood pressure reading below 140/90 mm Hg during the survey, as a directly age standardized percent of all with high blood pressure, for calendar years 1998–2002, standardized using the England 2001 census noninstitutional adult population count (*Source*: HSE).
 - (3) Indirectly age and sex standardized rates of emergency admissions of patients to hospital with a stroke (primary diagnosis international classification of diseases (ICD) version 10 (ICD-10) codes I61–I64) per 100 000 residents of all ages, for FY 1998/1999–2003/2004, standardized to 2001/2002. The denominators are mid-year population estimates for 1998–2002 (*Source*: HES, ONS).
 - (4) Indirectly age and sex standardized percent of emergency readmissions of patients of all ages to any hospital between 0 and 27 days (inclusive) of live discharge following admission with a stroke (primary spell diagnosis ICD-10 I61–I64), for FY 1998/1999–2003/2004, standardized to 2001/2002 (*Source*: HES).
 - (5) Indirectly age and sex standardized rates of deaths occurring in hospital and after discharge among patients of all ages, between 0 and 29 days (inclusive) of an emergency admission with a stroke (primary spell diagnosis ICD-10 I61–I64) per 100 000 CIPS, for FY 1998/1999–2003/2004, standardized to 2001/2002 (*Source*: HES, ONS).
 - (6) Indirectly age and sex standardized percent of continuous inpatient spells (CIPS) for patients of all ages with an emergency admission with a primary diagnosis of stroke (ICD-10 codes I61–I64), where the patient was discharged to the preadmission category of accommodation between 0 and 55 days (inclusive) of admission, for FY 1998/1999–2003/2004, standardized to 2001/2002 (*Source*: HES).
 - (7) Directly age standardized mortality rate from stroke (ICD-10 codes I60–I69, ICD-9 codes 430–438) per 100 000 residents of all ages for 1998–2003, standardized to the European standard population. These ICD codes are different from those used for stroke in the HES based indicators. HES has ICD-10 coding across all years while ONS deaths data do not, and there is no equivalent for ICD-10 I61–I64 in ICD-9. Years 1998 and 2000 use ICD-9, and years 1999, 2001 and 2002 use ICD-10. Data based on ICD-9 are adjusted for equivalence to ICD-10 (*Source*: ONS).

See the *Compendium of Clinical and Health Indicators*, www.ncho.d.nhs.uk for further details on indicators and methods.

(d) Fitting a linear trend to log transformed rates.

and for each year) at the level of NHS Strategic Health Authority (SHA) (populations 1–2.5 million), NHS Primary Care Organization (PCO) (populations 65 000–375 000) or Local Authorities (LA, local government, populations 25 000 to 990 000). The data for the latest year are accompanied by **confidence intervals**, showing that some of the minimum and maximum values are statistically significantly different from the England value. For example, the maximum PCO rate of deaths after admission to hospital with stroke, 42 241.5/100 000, is statistically significantly higher than the England average of 25 974.3/100 000. Sometimes, confidence intervals at organizational level may be wide due to errors in **estimation** when small numbers of cases are involved and differences in rates may not be statistically significant (see methods, annex 3, in the *Knowledge Base*) [6]. The number of stroke deaths at PCO level is sufficiently large for this not to be an issue.

Figure 2 shows geographical variation between PCOs in England, grouped in Office for National Statistics (ONS) Area Groups. Each dot represents a PCO. The line around each dot represents 95% confidence intervals around the death rate. The standardised death rate is an estimate and the true value is likely to be within the interval with 95% probability. In visual terms, if the confidence intervals of a PCO value do not overlap those for England, the PCO value is considered statistically significantly different from the England one. When comparing geographical areas, it is important to compare “like” with “like”, hence the grouping of PCOs by ONS Area Groups. The ONS has used cluster analyses to create an area classification for grouping PCOs that are most similar in terms of 42 demographic, socioeconomic, housing, and other census 2001 variables [7]. Figure 2 shows that there is substantial variation between “like” PCOs, suggesting that factors other than population or environment may influence these rates, such as quality of health care. There may also be differences in the quality of data submitted by different organizations that need to be taken into account when interpreting organizational variations [8].

Table 2 shows statistically significant differences in indicator values at England level by gender and social deprivation. The latter is based on the index of multiple deprivation [7]. These are aspects that managers and policy makers need to take into account.

Some may reflect varying risk, others poorer quality of service delivery. Where variation reflects different levels of risk that is not amenable to health care, (e.g., older people being at higher risk of developing a stroke), indicators that involve comparison between organizations, or over time need to be adjusted to reflect such differences in risk between the populations being assessed. The indicators in Table 1 have, in general, been standardized by age and sex.

Statistics for Monitoring Achievements – Breast Cancer

There have been several recent commitments to improving cancer services and outcomes (such as the NHS cancer plan). The overall target for reducing the disease burden is expressed in terms of mortality, but mortality trends reflect both the incidence of cancer and the survival of cancer patients. Mortality is not the best indicator to measure the progress of health services in treating those with the disease.

Table 3 contains a set of indicators, drawn from NCHOD’s *Compendium of Clinical and Health Indicators* [3] that provide a more detailed insight as follows:

- Large numbers of new patients diagnosed with breast cancer each year, with no statistically significant change in rates over the years. There is substantial variation in incidence rates between Local Authorities.
- On average, around three quarters of all eligible women in England who are offered screening for breast cancer take it up. In a recent year, this take-up varied from 27% to 86% between PCOs, as shown in Figure 3.
- A statistically significant falling trend (improvement) in deaths from breast cancer.
- Around a fifth of women dying from breast cancer die at home. This varies from 4% to 46% between PCOs and may reflect patient and family choice, availability of hospices and community support and so on. There are quality of dying implications.
- A statistically significant rising trend (improvement) in five-year survival after diagnosis of breast cancer.

Relative survival for a particular period is an estimate of the proportion of cancer patients who

^(a)Sources of data: hospital episodes statistics. The Information Centre for health and social care

survive their disease after adjustment for death from other causes (that is, the ratio of the survival rate observed to that which would have been expected if cancer patients had the same overall mortality as the general population). Relative survival can be directly standardised for age to take into account variation in survival by age and changes in the age distribution of cancer patients over time or between areas. At the time of their publication, cancer survival indicators will reflect the impact of past as well as current health care, over the five years from diagnosis. Trends and geographical variation may be due to several factors including the quality of primary care, the speed of referral, and the quality of treatment

services. The survival rates may also be a proxy for other factors not readily measured, such as the local population's level of understanding of cancer symptoms and what to do about them, variations in the extent of disease at diagnosis (stage) and in the histology and grade of tumours, and artefacts in the data.

Not enough is known about the causes of breast cancer and the potential to prevent it. However, early detection and timely, high quality treatment can make a difference to survival. The substantial variation between geographical areas and comparisons with other countries show that there remains scope for improvement.

Statistics for Monitoring Achievements – Mental Health

Monitoring the quality of mental health care is problematic. Deaths are low, so indicators based on the number of deaths are inadequate. Table 4 shows statistically significant falling death rates from suicides and undetermined injury but this is an inadequate reflection of all of mental health care. Much of mental health care occurs outside the hospital and there is little by way of routine **data collection** on activity or outcomes. Also, there are few explicit standards. The challenge is to find a way of using routine data from hospitals to make some inferences about both hospital and community care and to identify aspects of care that are materially below optimum. National service guidelines for mental health highlight the preference for community over hospital care. With this policy being expected to produce better outcomes, assessing the way the service for mental health is delivered may be used as a proxy for quality of care.

Mentally ill patients vary in the number of readmissions to hospitals and time spent in hospital, and these may reflect variations in the quality and availability of care and support in the community. Too many readmissions and long cumulative lengths of stay may reflect inadequate community care, but too few readmissions and short cumulative lengths of stay may reflect inadequate provision of necessary hospital care. A combination of the total number of admissions and the total time spent in hospital by patients during a year could be used to assess this. There may well be a trade-off between time spent in hospital and frequency of admission, and it is therefore important to consider the balance between the two variables as well as the individual measures. Studies of observed variation between populations could be used to derive target ranges for optimum patterns of care.

Table 4 shows sets of indicators for adults and older people that have been constructed by linking hospital data for individual patients over 1 year. The starting point for each patient is a first admission to hospital for psychiatric care between April and June during the year of assessment, with follow up for 12 months after the date of the first admission. The averages for all patients within a geographical area for the total number of days spent by patients in hospital and the total number of admissions per person during 12 months have been calculated.

Readmissions could be to any NHS hospital in England and for any condition, such as injury, not just mental illness.

Figure 4 shows that there is substantial variation between primary care organisations for each of the two variables. To give each component equal weight, they were transformed into a modified version of a statistic called a “z score” (by measuring the distance from a defined reference point and dividing by the standard deviations of the individual distributions). Conventionally, the mean of a distribution is the reference point for z scores. However, the mean is not necessarily a suitable target for a performance score because it is partly a reflection of “poor performance” at the tail end of the distribution. Reference points that are assumed to reflect an “optimum” may be more appropriate. Modified z scores, in which the reference points were 1.96/1.94 admissions per person and 59.76/71.99 days total stay in hospital during 12 months (for adults/older people respectively), were calculated. These reference points were selected as a realistic joint target because they had been actually achieved by a Strategic Health Authority in 2001/02 (the financial year selected as standard). This “best achieved combination” of a low rate of admissions per person and a low total stay per person, giving each the same level of importance, equates to the lowest composite z score at the level of strategic health authority, although at the level of primary care organisation, some achieved even better z scores. These reference points were used to calculate modified z scores across all 6 years.

The z scores measure how far each primary care organization is from the defined optimum for each of total admissions and total stay. A composite score was then produced for each organisation by adding its two z scores, equating to a summary of that organisation’s mix of experience on two fronts. A high composite score would be considered undesirable as it would indicate more hospitalisation than expected. Two organisations with a different mix of values for admissions and length of stay may have the same composite z score, reflecting the same performance but different trade-offs. Improvement over time should lead to lower overall composite z scores and a reduction in variation. Table 4 shows statistically significant worsening trends in composite z scores at the England level for both, adults and older people over six financial years. There is also substantial variation between primary care organizations.

Figure 4 Geographical variation in the relationship between frequency of hospital admission and total time spent in hospital over one year by mental health patients

A possible cause of variation between primary care organisations might be differences in the prevalence of illness and in the level of support provided in the community, both by professional bodies and informal networks such as families. A full assessment of the effect of such factors is difficult, however, a comparison of similar geographical areas may help. For example, the populations of big cities can be more transient, have a greater incidence of some mental illnesses, and have fewer informal networks. The Office for National Statistics has used cluster analyses to create an area classification for grouping primary care organisations that are most similar in terms of 42 demographic, socioeconomic, housing, and other census 2001 variables. Figure 5 shows the composite modified z score for each primary care organisation grouped within its area group. Although it shows some differences between groups, there is much greater residual variation within each group, suggesting that influences other than demography and socioeconomic conditions are largely responsible for the variation, such as service availability and clinical practice.

The overall conclusion is that while there is a policy (with implied benefit) for care for mental health patients to take place in the community, there is a growing trend in hospitalisation and substantial variation between geographical areas. These may reflect both the availability and quality of health and social care for such patients and need further investigation. This example also shows how existing routine data may be used creatively for policy and management purposes.

Gaps in Data

Figure 1 shows a number of gaps in existing stroke related data. For example, there are no routinely collected data, at national level, on new patients with stroke that are treated in the community, making measurement of the incidence of stroke and hence what is achieved through preventive services, incomplete. Similarly, there are no data on levels of disability, impact on quality of life, and consequences of poor quality care after a stroke, for example, pressure sores, aspects which are highly important to patients. A multi-disciplinary working group, involving clinicians, policy makers, managers, researchers, representatives of patients, and others, established to

advise on data that should be collected, made recommendations for 29 indicators that could be produced to monitor all aspects of clinical and health outcomes [9]. Many of these indicators will need new data collection.

Two further working groups, on breast cancer and severe mental illness have also recommended indicators along the same lines [10,11]. While these reports are now eight years old and need updating, they illustrate how achievements of health care may be monitored more comprehensively. Recommendations for indicators related to breast cancer, for example, included:

- Indicators related to improvement of early detection and treatment of breast cancer:
 - incidence of primary breast cancer by cancer stage at diagnosis
 - detection rate of small primary breast cancers
 - incidence of interval breast cancers
 - incidence of invasive breast cancer following treatment for ductal carcinoma in situ.
- Indicators related to reduction of death and complications from breast cancer and its treatment
 - survival rates by cancer stage at diagnosis
 - population-based death rates from breast cancer in women
 - percentage of patients, diagnosed as having breast cancer, who had received a diagnostic triple assessment
 - percentage of patients with breast cancer under the care of a breast cancer specialist
 - percentage of patients receiving treatment for breast cancer whose care was planned jointly by a multi-disciplinary group
 - percentage of patients who, having undergone potentially curative surgery for breast cancer, were given chemotherapy as part of their primary treatment
 - recurrence rates of breast cancer by site and type of primary surgery
 - Rates of specific complications detected, within one year of discharge from hospital, among patients having undergone in-patient treatment for breast cancer
- Indicators related to maintenance of well-being during and following treatment for breast cancer.

Figure 5 Geographical variation, within and between clusters of populations with similar socio-demographic characteristics, in a hospitalisation score for mental health patients

- delays from patient identification of symptoms to start of treatment for breast cancer
- patient satisfaction with specific areas of the management of their breast cancer care
- assessment of health-related quality of life within a population of patients one year after diagnosis of breast cancer
- assessment of psychological distress in the patient following treatment for breast cancer.

Where routine data are not available at the national level, policy makers and service providers may need information on existing independent datasets and guidance on how to undertake their own measurements and data collection to fill in gaps. NCHOD provides a list and selective review of the quality of existing databases in the UK (*Directory of Clinical Databases (DoCDat)*), some of which are voluntary with only part coverage across the country [12]. Such databases, for example, the Royal College of Physicians national stroke audit, can be alternative sources of data for such monitoring. NCHOD also provides a bibliography of the research literature on the measurement of outcomes from a patient's perspective, plus guidance on how to select and use relevant measurement instruments [13].

Conclusions

This brief article has shown the kinds of outcome related questions that policy makers and managers ought to be asking about health care. The focus has been on what is achieved through resource use. The role of statistics in monitoring this, and constraints in the availability and use of statistics have been illustrated using data on stroke, breast cancer, and mental health from the NHS in England. Information on outcomes is one part of wider monitoring, covering the organization of services; resources available; access to and quality of service delivery; and patient perspectives, including their satisfaction with the services provided. This article is of necessity, an oversimplification of what are in reality, extremely complex systems and issues.

Statistical Issues in Vaccine Safety Evaluation

Introduction

Mass vaccination programmes have greatly reduced the incidence of many common infections of childhood. However, since vaccines are often administered to healthy children, there is heightened public interest in their safety. Because vaccines are used on a large scale, rare reactions can result in substantial numbers of adverse events, with potentially disastrous consequences for public confidence in vaccination programmes. Evidence of safety, and rapid identification of potential problems, are thus essential to the success of vaccination programmes. In this article, some of the statistical methods used for monitoring vaccine safety are described.

Prelicensure Evaluation of Vaccine Safety

Vaccines are evaluated rigorously for safety and efficacy prior to being licensed. At the developmental stage, an experimental vaccine is evaluated extensively in the laboratory. Once sufficient data have been accumulated in the laboratory, the new vaccine is evaluated in humans. Since the 1940s, such evaluations have been based on the methodology of **clinical trials** [1].

Phase I and Phase II Studies

Phase I studies are the first trials in which the experimental vaccine is used in humans. They are usually conducted in small numbers of adult volunteers. In view of their small size, the safety data available from phase I trials is limited to documenting common reactions and identifying serious or unusual side effects.

The next stage is to evaluate the vaccine in phase II studies, which are conducted in those individuals for whose benefit the vaccine was developed. Phase II studies are usually comparative, involving one or several vaccine groups and a control group, and are undertaken using the methodology of double-blind, randomized controlled trials [2]. Phase II trials are of appreciable size, typically including 50–500

participants. However, sample sizes of this order are sufficient only to compare rates of common adverse reactions.

Phase III Trials

The primary purpose of a phase III vaccine trial is to assess the protective efficacy of the vaccine, and to provide further evidence of safety. Phase III trials typically involve 1000–50 000 participants. They are usually double blind and randomized. A phase III trial provides a unique opportunity to assess the safety of the vaccine in a large study under experimental conditions. However, even the largest phase III vaccine trials are too small, and follow-up periods are too short, to provide robust evidence of safety in respect of rare adverse events, or delayed events. This must be achieved by surveillance after the vaccine is licensed.

Postlicensure Surveillance of Vaccine Safety

Once a vaccine has been shown to be effective, is licensed and is recommended for routine use in mass vaccination programmes, it is necessary to monitor its safety using epidemiological surveillance.

Two Examples

Surveillance is necessary both to identify rare or delayed adverse events that cannot be picked up in clinical trials, and to monitor safety more generally.

Example 1 The Cutter Incident. The 1954 field trial of the Salk inactivated polio vaccine remains to date one of the largest vaccine trials ever undertaken. The trial involved 1.8 million children in the United States, of whom 400 000 were randomly assigned to vaccine or placebo, and the remainder enrolled in an open study. On April 12, 1955 the Salk vaccine was declared to be safe and effective. The vaccine was licensed and mass immunization began a few days later. On April 26, reports were received of children who had become paralyzed after receiving polio vaccine from batches made by Cutter Laboratories. It was found that a production fault had caused live virus to enter these vaccines, causing 163 cases of paralysis and 10 deaths, and undermining public

confidence in an otherwise safe and effective vaccine [3, 4].

Example 2 Swine Flu Vaccine and Guillain-Barré Syndrome. In 1976 concern grew in the United States that an epidemic of influenza A virus of a type commonly known as *swine flu* was about to occur. Accordingly the authorities organized a mass vaccination campaign using swine flu vaccines. Between October 1 and mid-December, some 45 million doses of vaccine were administered. However, on December 16 the immunization programme was suspended following reports of Guillain-Barré syndrome (GBS), an uncommon disorder resulting in paralysis of the limbs, occurring in close temporal relation with swine flu vaccination [5].

Note that in both the Cutter incident and the swine flu episode, the association between vaccination and the adverse event became apparent from spontaneously reported instances of adverse events by medical personnel, owing to the close temporal relationship between vaccination and the adverse event.

Temporal Association and Spontaneous Reporting Systems

Spontaneous reporting systems rely on individuals reporting adverse events which they believe may be causally associated with particular vaccines. Such systems have been formalized in several countries, for example through the “Yellow Card” system in the United Kingdom and the Vaccine Adverse Event Reporting System (VAERS) in the United States [6].

Spontaneous reporting systems, however, suffer from two main shortcomings. First, it is seldom possible to attribute **causality** or estimate effect parameters such as relative risks, since the data are not controlled. It is sometimes possible, however, to identify changes in reporting patterns, using measures such as proportional reporting ratios [7]. A second shortcoming is that reporting may be incomplete or inaccurate. This may mean that some adverse events are missed, or that their importance is underestimated. The experience of Urabe mumps vaccines and aseptic meningitis is a case in point.

Example 3 Urabe Mumps Vaccine and Aseptic Meningitis. Measles, mumps, and rubella (MMR) vaccines were introduced in the United Kingdom in 1987. Spontaneous surveillance methods had

suggested that there was a small risk (between 0.4 and 10 per million doses) of aseptic meningitis after mumps vaccine. A subsequent study found that the true risk of aseptic meningitis in the period 15–35 days after receipt of an MMR vaccine containing the Urabe mumps strain was much higher, about 1 in 11 000 doses [8]. As a result of this finding, Urabe-containing vaccines were replaced by other types of vaccines for which there was no evidence of an association with aseptic meningitis.

Following this experience, active surveillance methods based on record linkage between hospital and vaccination databases were put in place, to provide more reliable estimates of postvaccination risks than those available from spontaneous reporting systems [9].

In most instances, adverse events may occur for reasons unconnected with vaccination. Thus, observing a temporal association provides no evidence of causal association. To demonstrate a causal association, it is necessary to estimate the rate at which events occur in temporal association with vaccination, relative to the rate at which they would have occurred in the absence of vaccination, and provide convincing statistical evidence that this relative rate is greater than 1. The following controversies exemplify the risks of placing too much reliance on close temporal association as an indicator of causality.

Example 4 DTP Vaccine and Brain Damage. The diphtheria-pertussis-tetanus (DTP) vaccine was introduced in the United Kingdom in the 1950s, leading to a large reduction in whooping cough. By 1974, 81% of children in the United Kingdom were vaccinated with the DTP vaccine. However, in 1974, public confidence in the vaccine was undermined following intense media coverage of a report describing 36 cases of neurological complications occurring in close temporal association with DTP vaccination [10]. The idea took hold that DTP vaccine caused brain damage, and as a result the coverage of the vaccine dropped sharply to 31%, resulting in the reemergence of whooping cough epidemics. However, subsequent epidemiological investigations and close scrutiny of the evidence led to the conclusion that severe side effects of the DTP vaccine, including brain damage, are so rare that they defy measurement [11].

Example 5 MMR Vaccine and Autism. In 1998, a report was published suggesting that MMR vaccine might cause autism. This report was based on 11 children who were reported to have suddenly experienced serious behavioral problems within 2 months of receiving the MMR vaccine [12]. The report received wide publicity in the media, and generated a controversy that threatened to undermine the MMR vaccination campaign. MMR vaccine coverage dropped from 92 to 60% in some areas, measles outbreaks occurred resulting in the first death from measles in a decade. Several large epidemiological studies were undertaken, none of which confirmed the association between MMR vaccination and autism [13–15].

In both examples, much publicity was given to serious adverse events occurring shortly after vaccination. However, subsequent epidemiological investigations did not confirm a causal link. It is reasonable to conclude that the observed temporal associations were chance events, the incidence of the events coincidentally peaking at the recommended ages for vaccination.

Postlicensure Study Designs for Evaluating Vaccine Safety

Surveillance systems based on spontaneous reporting play an important role in monitoring vaccination programmes and generating hypotheses. However, they can seldom be used for testing hypotheses and providing reliable estimates of vaccine-associated risks, owing to reporting biases and the difficulty in establishing appropriate baseline rates. Instead, epidemiological studies are required.

Cohort Studies

In **vaccine safety** evaluation, cohort studies are usually retrospective, based on preexisting databases such as the Vaccine Safety Datalink (VSD) database in the United States [16] and the General Practitioner Research Database (GPRD) in the United Kingdom [17], or using several databases combined by record linkage techniques. Two basic types of cohort studies are used: parallel group and risk-interval cohort studies.

Example 6 Organic Mercury in Vaccines and Developmental Disorders. Some vaccines contain

thiomersal, a preservative made from ethyl mercury. Concern has been expressed that the administration of vaccines containing thiomersal might cause developmental disorders in later life. A retrospective parallel group cohort study was undertaken [18]. Exposure groups were defined according to the cumulative dose of ethyl mercury received through the administration of thiomersal-containing vaccines by age 6 months. The subsequent occurrences of developmental disorders in the different exposure groups were then analyzed using **survival analysis** techniques, including Cox regression [19]. Little evidence was found that exposure to thiomersal-containing vaccines cause neurodevelopmental disorders.

In many cases, the biological mechanism through which a vaccine may cause adverse events is short lived. Thus it is appropriate to represent the putative vaccine effect by a step function taking a value β within a predefined risk period after vaccination, and 0 outside this risk period. The value β is the logarithm of the hazard ratio (or incidence ratio) over the risk period. In some cases, it is appropriate to use several risk periods, to represent different effects, or to obtain a more accurate impression of how the vaccine-associated risk varies with time since vaccination. Exposure is thus a time-varying **covariate**.

Example 7 Sudden Infant Deaths and DTP Vaccine. The possible association of DTP vaccine and sudden infant death syndrome (SIDS) was investigated in a risk-interval cohort study [20]. Four post-vaccination risk periods were used: 0–3, 4–7, 8–14, and 15–30 days postvaccination. Other times were allocated to the baseline or control period. There was no evidence of a positive association between DTP vaccination and SIDS: for the 0–3 day risk period, for example, the hazard ratio was 0.18, with 95% **confidence interval** (CI) (0.04, 0.8).

The apparent protective effect in this study may be due to a selection **bias**, immunizations being postponed if the child is in poor health. Such biases potentially affect all risk-interval methods [21].

Case–Control Studies

For rare adverse events, cohort studies require access to very large databases. Case–control studies thus represent an attractive alternative, and are commonly used for the evaluation of vaccine safety [22]. In view of the importance of age effects, especially

for the evaluation of pediatric vaccines, case-control studies are usually individually matched on date of birth, and analyzed by conditional logistic regression [23]. Exposures within each case-control set are determined according to vaccination history prior to the index date, namely the date of onset for the case. Case-control studies for vaccine safety evaluation, like cohort studies, can be broadly classified into two categories according to whether or not the putative vaccine-associated risk is believed to be time limited after vaccination.

Example 8 MMR Vaccination and Autism. A large case-control study was undertaken within the GPRD to investigate the association, if any, between MMR vaccination and autism [15]. One thousand two hundred and ninety-four cases were included, individually matched to up to five controls per case on year of birth, sex, and general practice. The primary exposure variable was ever having received MMR vaccine: thus, in this analysis, the postvaccination risk period is assumed to be unlimited. The adjusted odds ratio was 0.86, 95% CI (0.68, 1.09).

Example 9 Hepatitis B Vaccination and Multiple Sclerosis. Mass vaccination against hepatitis B was introduced in France in 1994, targeted at infants and older children, with a catch-up vaccination programme in adults. By July 1996, 200 cases of multiple sclerosis occurring within 2 months of a hepatitis B vaccination had been reported. Several studies were subsequently undertaken to assess the risk of multiple sclerosis following hepatitis B vaccination.

One case-control study involved 236 new cases of multiple sclerosis and two or three controls per case individually matched on age, gender, date, and center of referral [24]. Two exposures were used: hepatitis B vaccination 0–2 months or 2–12 months prior to the index date. These choices reflect the belief that the postvaccination risk is time limited, and is highest in the 0–2-month risk period after vaccination. A raised but nonsignificant odds ratio was found for the 0–2-month period: 1.8, 95% CI (0.7, 4.6), though when the analysis was restricted to individuals with vaccination certificates the odds ratio dropped to 1.4, 95% CI (0.4, 4.5).

As shown in this example, it is important in all vaccine safety studies, but particularly in risk-interval studies, to use documented (rather than self-reported) data on vaccination histories.

Studies Using Only Cases

A variety of statistical methods based only on cases have been used for evaluating vaccine safety, often exploiting the natural experiments resulting from changes in vaccination schedules [25]. Two generic methods are particularly attractive because they automatically control fixed confounders. These are the self-controlled case series method [26, 27] and the case-crossover method [28]. The self-controlled case series method is derived from a Poisson risk-interval cohort model by conditioning on the total number of events experienced by each individual in the cohort, from which only the cases are informative. The method allows for adjustments for age. In contrast, the case-crossover method is a version of a matched case-control study in which control periods are sampled from the life history of the case prior to the event. In this method it is assumed that there is no time trend in the probability of vaccination.

Example 10 Rotavirus Vaccine and Intussusception. In 1998 a new vaccine against rotavirus infection was introduced in the United States. After receiving reports of intussusception soon after vaccination, the vaccination programme was suspended and an epidemiological study was undertaken [29]. A case series analysis of 432 cases was conducted, with observation period 1–12 months of age. The risk periods 3–7, 8–14, and 15–21 days after each dose of vaccine were used. The analysis found a relative incidence of 58.9, 95% CI (31.7, 110), for the 3–7-day risk period after the first dose, thus confirming a significant association between rotavirus vaccination and intussusception in infants.

Self-controlled cases series work best when the risk period or periods used are short compared to the observation period, namely the period over which cases are ascertained. However, in some circumstances, the method may be used with indefinite risk periods [25, 30].

The self-controlled case series method controls for age effects. In the parametric version of the model these effects are represented by a step function. In the semiparametric model, they are unspecified [31]. Allowing for age effects is essential when dealing with adverse events relating to pediatric vaccines, since the incidence of such events is usually highly age dependent. Since pediatric vaccines are usually administered according to a schedule, vaccination

rates are also highly age dependent, precluding the use of case-crossover methods. However, in adult populations, age effects may be less important, and the case-crossover method may be used.

Example 11 Hepatitis B Vaccine and Relapses in Multiple Sclerosis. A case-crossover study was set up to investigate the possible association between a range of vaccinations, including hepatitis B vaccination, and relapses in multiple sclerosis [32]. Vaccination histories were obtained from 643 individuals with multiple sclerosis who suffered a relapse in 1992–1997. The case period was defined as the 2 months preceding the relapse. The 8 months prior to the case period were split into four 2-month control periods. Hepatitis B vaccination in the case and control periods were documented, and analyzed as in a case–control study under the assumption that vaccination rates did not vary appreciably over the 10-month age range spanned by the control and case periods. The odds ratio for the association between hepatitis B vaccination and relapse was 0.67, 95% CI (0.20, 2.17).

Wider Statistical Issues

Vaccines are to some extent the victims of their own success. After an effective vaccine is introduced, the perceived balance of risks and benefits shifts as memories of the disease fade, to be replaced by more immediate concerns about potential risks. This raises some wider issues. First, evidence of safety or lack of it is often required quickly. Thus, timeliness is an important consideration, as well as statistical **power**. Second, evidence of safety can never be absolute, since it is not possible scientifically to prove that administration of a vaccine carries zero risk. Thus statisticians working on vaccine safety issues must be prepared to engage in a public evidence-based discussion about risks and benefits.

Self-Controlled Case Series Analysis

Introduction

The self-controlled case series method or case series method for short, was developed by Farrington [1] to investigate rare adverse events associated with routine childhood immunizations. It has been used in several areas of epidemiology, for example, in **vac-****cine** safety studies by Farrington *et al.* [2], Miller *et al.* [3], and Andrews [4]; in nonvaccine pharmacoepidemiology by Mullooly *et al.* [5], Hubbard *et al.* [6], and Hocine *et al.* [7, 8]; and Becker *et al.* [9] used the method to investigate the association between long-haul flights and thromboembolism. However, the case series method can be used more widely, to study associations between adverse events and any time-varying exposures as shown by Farrington and Whitaker [10].

The main advantages of this method are that it is based on data from cases only, it implicitly adjusts for all fixed confounders, and in some circumstances it has high efficiency relative to the cohort method. The case series method combines aspects of the case-control and cohort methods, using retrospectively ascertained exposure histories in cases to estimate the relative incidence (RI) in intervals during or in some defined period after exposure, relative to a control period, as described below.

Case Series Method

The self-controlled case series method is based on data on cases only, but may be derived from an underlying Poisson cohort model as follows. Consider a cohort of individuals who may experience the adverse event of interest over a defined observation period $[c_i, d_i]$. We assume that data are available on event times and exposure histories over the entire observation period (note that exposures occurring after an event are required as well as those occurring prior to an event). For each individual i , the observation period $[c_i, d_i]$ is split into intervals for age-groups j , $j = 0, 1, 2, \dots$ and risk periods k , where $k = 0$ for control periods and $k = 1, 2, \dots$ during exposure risk periods, when an individual is deemed to

be at increased (or reduced) risk compared to control periods. Let n_{ijk} and e_{ijk} denote respectively, the number of events experienced and the time spent by individual i in age-group j and risk period k . Within each such interval, the incidence

$$\lambda_{ijk} = \exp(\varphi_i + \alpha_j + \beta_k) \quad (1)$$

is assumed to be constant and the number of events n_{ijk} is assumed to be Poisson with rate $e_{ijk}\lambda_{ijk}$. In equation (1), φ_i represents an effect for individual i , α_j the effect associated with age-group j , and β_k the effect associated with risk period k , with $\alpha_0 = \beta_0 = 0$. The incidence function (1) during the baseline period is thus $\lambda_{i00} = \exp(\varphi_i)$. The exponentiated quantities $\exp(\beta_k)$ are referred to as *relative incidences*.

Conditioning on the number of events $n_i = \sum_{j,k} n_{ijk}$ observed for individual i during $[c_i, d_i]$, the likelihood is product multinomial with kernel:

$$L(\alpha, \beta) = \prod_{i=1}^N \prod_{j,k} \left(\frac{e_{ijk} \exp(\alpha_j + \beta_k)}{\sum_{r,s} e_{irs} \exp(\alpha_r + \beta_s)} \right)^{n_{ijk}} \quad (2)$$

where N is the number of cases. Note that the individual effects φ_i (which encompass any time-independent confounders) cancel out. Only age (or other time-dependent covariates) need to be modeled, though it is possible to include fixed confounders as interactions with the exposure effect. It should be noted that individuals i with no events ($n_i = 0$) in $[c_i, d_i]$ do not contribute to the conditional likelihood in equation (2), and hence only cases within the underlying cohort need be sampled.

The case series method may also be applied to rare nonrecurrent events. In this case, λ_{ijk} in equation (1) is a hazard function representing the incidence in individuals who have not experienced the event, rather than a Poisson rate. However the log likelihood (2) is valid in the limit $\varphi_i \rightarrow -\infty$. This is because recurrent and nonrecurrent events effectively become indistinguishable except in very large samples. Thus, rare nonrecurrent events may be analyzed using the case series model. For more details see Farrington and Whitaker [10].

2 Self-Controlled Case Series Analysis

Example: ITP and MMR Vaccine

Idiopathic thrombocytopenic purpura (ITP) is a rare, potentially recurrent adverse event, in which abnormal bleeding into the skin occurs due to low blood platelet count. In rare instances, measles, mumps, and rubella (MMR) vaccine is thought to cause ITP. The data in this example are described in Farrington and Whitaker [10], and relate to the first ITP in 35 children aged 1–2 years with MMR histories. The observation periods ran from age 366 to 730 days. In this example, three age-groups are used: 366–487 days ($j = 0$), 488–609 days ($j = 1$),

As an illustration, consider the first child ($i = 1$), who was vaccinated at age 670 days and suffered a first ITP at age 691 days. Figure 1 shows the observation period of this child which was split into seven consecutive intervals according to age and exposure group. The details, together with the corresponding Poisson rates λ_{1jk} are given in Table 1.

The likelihood contribution for child 1 is based on the multinomial probability that the event occurred in the fifth interval (at age 691 days), given that it occurred during his or her observation period:

$$L_1(\alpha_2, \beta_2) = \frac{14e^{\alpha_2 + \beta_2}}{34 + 122e^{\alpha_1} + 60e^{\alpha_2} + 15e^{\alpha_2 + \beta_1} + 14e^{\alpha_2 + \beta_2} + 14e^{\alpha_2 + \beta_3} + 18e^{\alpha_2}} \quad (3)$$

and 610–730 days ($j = 2$). Three 2-week-long post-MMR risk groups were defined: 0–14 days after vaccination ($k = 1$), 15–28 days after vaccination ($k = 2$), and 29–42 days after vaccination ($k = 3$). Multiple risk periods are used here to differentiate between phases of varying severity postvaccination. The control period for each child ($k = 0$) includes all other times within its observation period.

Table 1 Age and exposure intervals and Poisson rates for child 1

Interval (days)	Age level (j)	Risk level (k)	e_{1jk}	λ_{1jk}
[453 – 487]	0	0	34	e^{ϕ_1}
[487 – 609]	1	0	122	$e^{\phi_1 + \alpha_1}$
[609 – 669]	2	0	60	$e^{\phi_1 + \alpha_2}$
[669 – 684]	2	1	15	$e^{\phi_1 + \alpha_2 + \beta_1}$
[684 – 698]	2	2	14	$e^{\phi_1 + \alpha_2 + \beta_2}$
[698 – 712]	2	3	14	$e^{\phi_1 + \alpha_2 + \beta_3}$
[712 – 730]	2	0	18	$e^{\phi_1 + \alpha_2}$

The log likelihood for all 35 children is obtained in a similar way as for child 1.

The RIs for the postvaccination risk periods compared to the control period, which included all days in the observation period before and 43 days or more days after MMR vaccination are given in Table 2. The risk of hospital admission for first ITP was significantly raised 15 to 28 days after MMR vaccination. The overall significance of the vaccine effect may be tested using the likelihood-ratio test. The observed test statistic is 15.49 on 3 **degrees of freedom**;

Table 2 First ITP and MMR vaccine: relative incidence by risk period

Risk period (days after MMR)	Number of events	Relative incidence (RI)	95% confidence interval
Control	22	1	–
0–14	2	1.61	(0.36, 7.16)
15–28	8	7.18	(2.95, 17.49)
29–42	3	3.07	(0.86, 10.92)

Figure 1 Graphical representation of the observation period for individual $i = 1$ in the ITP and MMR vaccine data

reference to its asymptotic χ^2 (3) distribution yields a p value of less than 0.01.

This analysis was restricted to first ITP. In fact, five children experienced two ITP episodes and one child experienced five. Under the hypothesis that distinct episodes in the same child occur independently, the case series method can be used to analyze all 44 episodes in these 35 children. The results based on all episodes are shown in Table 3. The RIs are slightly lower than for the analysis of first ITPs. Finally, it might be objected that the small numbers of events in the risk periods call into question the validity of the asymptotic theory underpinning the calculation of **confidence intervals** and p values. To allay such concerns, **bootstrap** methods could be used. In a nonparametric bootstrap, cases are resampled with replacement. Alternatively, and more simply, the three postvaccination risk periods could be combined into one 0–42-day risk period. The corresponding RI is then 3.89 (1.79, 8.48) for first ITPs, and 3.23 (1.54, 6.75) for all episodes.

Properties and Implementation

Main Assumptions and Limitations

- The most important and limiting assumption of the case series method is that occurrence of an event does not alter the probability of subsequent exposure. Thus, exposures must be independent of prior events. In some circumstances, such as when an event alters the probability of exposure for only a short period, sensitivity to this assumption can be tested by including a pre-exposure “risk” period. See Farrington and Whitaker [10] for details.
- The observation period must be independent of event times. This can also be restrictive, for

example, if the event increases the short-term mortality rate.

- Events are assumed to arise in a nonhomogeneous **Poisson process**. In practice this is not very restrictive as generally events of interest are rare. Also, as noted above, the method can be used to analyze rare nonrecurrent events.
- It is only possible to estimate the RI: as in case–control studies, the absolute incidence cannot be estimated.
- Variability in the time or age of exposure and event between individuals is required.

Main Advantages

- The need to include only cases reduces **data collection effort**.
- An attractive feature of the case series method is that it is self-controlled; it implicitly adjusts on all non-time-varying confounders, such as genetic and socioeconomic factors.
- Time-dependent confounders such as age can be allowed for in the baseline incidence.
- The method may have high efficiency relative to the underlying cohort method.

Relative Efficiency

By conditioning on the number of events, the case series method loses some efficiency compared with the retrospective cohort method from which it was derived. However, under certain circumstances this loss of efficiency is small. Specifically, efficiency relative to the cohort method is high if the proportion of individuals exposed is high, the length of the risk periods are short in comparison with the observation period and the exposure effect is not large. It is not uncommon for such a situation to arise in practice. On the other hand, the method can be inefficient relative to the cohort method (for a fixed number of cases) if the risk periods are long in comparison with observation periods. Further details are given in Farrington and Whitaker [10].

Designing a Case Series Study

Designing a case series study requires prior specification of the risk periods, and of the observation period of interest. Risk periods are usually defined in relation to a prior hypothesis, which might be based on previous studies or other external knowledge on the

Table 3 All ITP episodes and MMR vaccine: relative incidence by risk period

Risk period (days after MMR)	Number of events	Relative incidence (RI)	95% confidence interval
Control	31	1	–
0–14	2	1.33	(0.31, 5.81)
15–28	8	5.99	(2.55, 14.07)
29–42	3	2.54	(0.73, 8.81)

effect of the exposure on the occurrence of the event. Observation periods are often defined implicitly by a combination of calendar time and age limits: for example, “all cases of acute asthma occurring in children aged 12–23 months inclusive between January 1, 2004 and December 31, 2006”. The observation period of such a case would then stretch from the later of 366 days of age and age (in days) on January 1, 2004 to the earlier of day 730 of age and age on December 31, 2006. Note that it is important to be precise in defining observation periods.

Exposure histories are then documented, using a data source that is independent of event occurrence. Note that all exposures with time at risk within each case’s observation period must be obtained. It is possible only to include cases with a history of exposure, provided that the risk periods of interest are short compared to observation periods (otherwise, there may be confounding between age and exposure effects, which nonexposed cases help to control). Thus, the method is particularly convenient for use with record linkage data based on imperfect identifiers, in which case it is desirable to include only definite matches.

Full details of sample-size formulas for the case series method are given in Musonda *et al.* [11]. Larger sample sizes are required to detect true exposure effects at the same **power** and **significance level** when the risk period is short relative to the observation period, the true RI is close to one, and in the presence of strong age effects, especially if they are monotonic.

Model Fitting

Suitable data, such as hospital admissions data, are usually assembled by listing one record per event. These data must be expanded to list each interval by individual i , age-group j , and risk-group k , along with the number of events that occurred during that interval n_{ijk} and the interval length e_{ijk} . The multinomial likelihood can then be fitted using a Poisson regression model with log link function. The number of events n_{ijk} is the response variable, the log time spent in an interval $\log e_{ijk}$ is offset and the model includes an individual effect γ_i to ensure the fitted total equals the observed values, the age-group effect α_j , and the risk-group effect β_k . The model is thus:

$$n_{ijk} \sim \text{Poisson}(e_{ijk}\lambda_{ijk}) \quad (4)$$

$$\log(\lambda_{ijk}) = \gamma_i + \alpha_j + \beta_k \quad (5)$$

Although this model can be fitted using most statistical software packages, it can be very slow if a study includes a large number of individuals. Fast methods for model fitting are available using the packages R, SAS, STATA, GENSTAT, and GLIM. Examples and instructions of how to expand the data and fit the models using these statistical packages are available from the self-controlled case series website: <http://statistics.open.ac.uk/scs/> [12].

Comparative Studies

The examples below compare the case series method with cohort studies. Example 1 shows the benefit of using the case series method compared to a full cohort study in reducing the data collection effort. Example 2 shows the advantage of using a case series analysis when information on confounders is incomplete.

Example 1: Febrile Convulsions and MMR Vaccine Barlow *et al.* [13] investigated the association between MMR vaccine and febrile seizures using a large cohort of 679 942 children under 7 years, living in the United States. The relative risk of first febrile seizure in the second week after MMR vaccine (8–14 days) was 2.83, with 95% CI (1.44, 5.55). A similar investigation undertaken by Farrington *et al.* [2], which used a case series study of 952 cases aged 12–23 months living in England, showed that the MMR vaccine was associated with febrile convulsions with a relative incidence of 3.04, 95% CI (2.27, 4.07). The case series study gives an estimate of RI close to the value obtained from the full cohort study, which included only 716 cases, but with a narrower confidence interval. When the exposure risk period is short in comparison to the observation period as in this example, the case series analysis has good efficiency relative to a cohort study. Although in this instance, the case series method has greater precision because the cohort study, though very large, included fewer events than the case series study.

Example 2: Asthma and Influenza Vaccine Kramarz *et al.* [14] used data from a cohort of 70 753 asthmatic children aged 1–6 years in 1996 living on the West Coast of the United States to determine whether influenza vaccination precipitates asthma exacerbations. The crude RI of asthma exacerbation

within 2 weeks after influenza vaccination was 3.29, 95% CI (2.55, 4.15), which decreased after adjustment for sex, age, calendar time, indicators of asthma severity, and preventive care practices to 1.39, 95% CI (1.08, 1.77). A case series analysis was undertaken using the 2075 children within the cohort who had at least one asthma exacerbation during the influenza season. The risk of asthma exacerbation within 2 weeks after influenza vaccination was found to be 0.98, 95% CI (0.76, 1.27). One interpretation is that the case series method controls fully for indication **bias** associated with the confounding effect of modeling asthma severity, children with more severe conditions being the most likely to receive the vaccine. In the cohort analysis, only partial control of such confounding may have been achieved.

Some Extensions of the Method

Semiparametric Model

There is also a semiparametric version of the case series model, which avoids misspecification of the age-specific baseline incidence [10]. In this model, the cumulative baseline RI is modeled by a step function with jumps $\exp(\alpha_r)$ at the distinct event ages for all N individuals combined s_r . The semiparametric likelihood for N cases, with case i experiencing n_i events at ages $t_{i1}, \dots, t_{in_i}$, is:

$$L(\beta) = \prod_{i=1}^N \prod_{j=1}^{n_i} \frac{\exp[\alpha_{ij} + \beta x_i(t_{ij})]}{\sum_r \exp[\alpha_r + \beta x_i(s_r)]} \quad (6)$$

where $x_i(t)$ is the exposure at age t for case i , and α_{ij} is the value α_r corresponding to t_{ij} ($j = 1, 2, \dots, n_i$ denotes an event for a specific individual and r denotes an event for any individual). An additional benefit of the semiparametric model is that it implicitly controls for exponential time trends: these are confounded with the age effects but do not influence the exposure effects.

For example, applied to the ITP data described earlier with a single post-MMR risk period of 0–42 days, the semiparametric model yields RI of 3.73 (1.60, 8.71) for first ITPs and 3.01 (1.38, 6.54) for all episodes.

Bivariate Counts

If two types of events, R and S , occur, the effect of an intermittent exposure on the occurrence of R rather

than S , may be evaluated by a conditional RI denoted RRc [8]. The RRc is defined as the ratio between RR^R and RR^S , the relative risks of R and S , respectively, and is estimated by the ratio of their estimates obtained separately by maximizing the appropriate log likelihood (1). The variance of the RRc estimate is simply the sum of the variances of the estimates of RR^R and RR^S under the assumption of independence of the counts of R and S . A test for checking such an assumption was proposed recently by Hocine *et al.* [7]. The test statistic was derived from a conditional likelihood using a bivariate Poisson-generated multinomial model. Robust **estimation** is described in Hocine *et al.* [15].

Other Methods Using Cases Only

Other methods have been proposed to investigate the relationship between an adverse event and a transient exposure using data only on cases. A review of case-only methods used in vaccine safety assessment may be found in Farrington [16]. Prentice *et al.* [17] derived a test for no association from a Cox proportional hazards model, but this test does not yield a readily interpretable association measure. Maclure [18] proposed the case–crossover method, a self-controlled case–control method in which a unique event time is matched to previous time intervals selected from the case’s history. This method yields consistent estimates using conditional logistic regression, only if the joint distribution of exposures is exchangeable as underlined by Vines and Farrington [19] and Whitaker *et al.* [20]. Feldmann [21] used a regression model for rare events with a constant baseline incidence. This model coincides with the case series method when the event of interest is rare and the baseline incidence is constant. A further close connection is to the work of Cox [22] on modulated Poisson processes. Cox’s conditional likelihood for a modulated process is identical to a case series likelihood for a single individual.

Early Detection Programs in Medical Care

Introduction

In recent years there is growing attention and interest in preventive medical care [1] as well as early detection programs (EDPs) or screening programs. A screening test is a special examination, which has the potential to diagnose disease while it is asymptomatic and the individual has no signs or symptoms. An EDP is a series of such exams. EDPs for many chronic diseases are now in place. This is especially true for a variety of cancer sites, most notably mammography to detect breast cancer, prostate-specific antigen (PSA) to detect prostate cancer, papanicolaou smears (Pap test) to detect cervical cancer, and fecal occult blood test for colorectal cancer, among others. The motivation for conducting EDPs is the expectation that early diagnosis will result in more cures and longer survival time. Consequently, accurately quantifying the benefit associated with an EDP is of major importance. Mathematical modeling of the disease-screening process, e.g., [2–12], allows us to investigate the performance of various EDPs and study their operating characteristics before we actually carry out any studies.

Different types of study designs, both experimental and observational, have been used to evaluate EDPs [13–15]. Ecological studies correlate mortality and the intensity of screening [16, 17]. Descriptive, uncontrolled studies, based on the experience of individual physicians, hospitals, and nonpopulation-based registries are common [18, 19]. The performance characteristics of various detection tests, i.e., their sensitivity, specificity, and positive predictive value, are generally first reported in such studies. The first evidence that screening may be successful is a stage shift, i.e., an increase in the incidence of early stage cancers coupled with a decrease in late-stage metastatic cancers; later, a reduction in deaths may occur. However, descriptive studies, which lack an appropriate control group and a proper sampling framework, cannot establish efficacy. More rigorous studies include randomized **clinical trials** (RCTs) and case-control studies, described in the sections titled “Case-Control Studies” and “Randomized Clinical Trials”, and a variety of prospective designs.

Prospective cohort studies are similar in many aspects to RCTs, but because the comparison groups are not established by **randomization**, they are generally more difficult to analyze and interpret. Examples of such trials are the UK trial of early detection of breast cancer [20–22] and the Nordic cervical cancer screening trials [23, 24], which showed an impressive reduction in incidence and mortality rate.

Notation and Modeling Assumptions

We consider an idealized model for the natural history of disease in which an individual can be in one of four states denoted by S_h , S_p , S_c , and S_d [2, 9]. An individual in the healthy state, S_h , is either disease free, or has a disease which cannot be detected. An individual in the preclinical state, S_p , has detectable disease but is unaware of it. An individual in the clinical state, S_c , has been diagnosed with disease. The state S_d corresponds to death due to disease. The natural history of disease is assumed to be progressive and is represented by the sequence $S_h \rightarrow S_p \rightarrow S_c \rightarrow S_d$. More generally the model can be embedded in a semi-Markov framework [25–27].

In our numerical calculations we assume that the sojourn time distributions in the various states are exponential with different parameters. Based on reported results [28–30] the mean sojourn times (in years) are given by 55 for S_h and 3.5 for S_p . The median sojourn in S_c is 10 years if the disease was detected by regular medical care and 17 years if the disease was detected by an early exam. For prevalent cases (cases detected at the first exam) the figures are 11 and 20 years respectively. The prevalence of pre-clinical disease is assumed to be 7 per 1000 per year. Examination for early detection are given at age(s) or time(s) τ and their sensitivity is denoted by β . These numerical inputs will be used below.

Case-Control Studies

General

The most common method, or study design, used to assess the benefit of screening is the case-control study [31]. Case-control studies for EDPs are conducted by sampling a group of cases and a group of matched controls and comparing them with respect to their screening history. In most studies cases are

2 Early Detection Programs in Medical Care

individuals that have died from the disease whereas the controls have not. The screening history is considered to be the exposure. Note that the definition of an exposure does not depend on whether the disease was actually diagnosed at a screening examination. The key is that both cases and controls are at risk for the outcome and the exposure [32]. For a review of current methodological approaches specialized to case–control studies for evaluating EDPs, see [33], which discusses many aspects of the design focusing on (a) the selection of cases and controls; (b) the definition of exposure; and (c) common biases. Typical biases associated exclusively with EDPs are length **bias** and lead time bias [2, 34–36]. The theoretical basis for the use of case–control studies for evaluating the benefit of screening has been investigated by [37], whose derivations we follow. For a large-scale simulation study to examine biases resulting from exposure definition, matching, and other factors, see [38].

Analysis

We model a case–control study assuming that individuals may have only one screening examination at a fixed age τ . The calculation involving multiple exams yields a qualitatively similar result. Let $E(\tau) = 1$ if the individual had an early detection exam at age τ and $E(\tau) = 0$ otherwise. Let T denote the follow-up time from the exam. The binary outcome variable is denoted by $D_\tau(T)$, i.e., $D_\tau(T) = 1$ if the individual dies of disease in the interval (τ, T) , and $D_\tau(T) = 0$ otherwise.

The odds ratio when the controls are defined as living individuals, with or without disease, is given by

$$\theta_u(\tau, T) = \frac{\Pr[E(\tau) = 1 | D_\tau(T) = 1] \Pr[E(\tau) = 0 | D_\tau(T) = 0]}{\Pr[E(\tau) = 1 | D_\tau(T) = 0] \Pr[E(\tau) = 0 | D_\tau(T) = 1]} \quad (1)$$

This quantity is observed in practice. The equality of the retrospective and prospective odds means that we can calculate the equation (1) theoretically using the expression

$$\frac{\Pr[D_\tau(T) = 1 | E(\tau) = 1] \Pr[D_\tau(T) = 0 | E(\tau) = 0]}{\Pr[D_\tau(T) = 1 | E(\tau) = 0] \Pr[D_\tau(T) = 0 | E(\tau) = 1]} \quad (2)$$

referred to as the *unrestricted odds ratio*. If the controls are defined as living individuals with clinical disease, the calculations are slightly modified. More formally, let $C_\tau(T) = 1$ if an individual is in the clinical state at T , and zero otherwise. In this population

$$D_\tau(T) + C_\tau(T) = 1 \quad (3)$$

for all individuals. The definition of the odds ratio is modified accordingly and conditions on the event equation (3). With some algebra we find that the odds ratio reduces to

$$\theta_r(\tau, T) = \frac{\Pr[D_\tau(T) = 1 | E(\tau) = 1] \Pr[C_\tau(T) = 0 | E(\tau) = 0]}{\Pr[D_\tau(T) = 1 | E(\tau) = 0] \Pr[C_\tau(T) = 0 | E(\tau) = 1]} \quad (4)$$

which we refer to as the *restricted odds ratio*. The derivation of the above probabilities is somewhat involved [37] and builds on the model for the natural history of the disease and the screening process.

Numerical Examples

We illustrate our calculations of the odds ratio using a hypothetical breast cancer screening trial, using inputs described in the section titled “Notation and Modeling Assumptions”. In Figure 1 we plot the inverse of the unrestricted odds ratio (equation (1)) as a function of the follow-up time for several screening ages and sensitivities. The plots for the restricted odds ratio are qualitatively similar.

Note that the odds ratio decays monotonically to unity as the follow-up time T increases. Cases diagnosed at large follow-up times T are likely to have developed the disease after age τ and an early detection exam has no effect for such individuals. Moreover it can be shown that

$$\sup_{T \geq \tau} \theta_u(\tau, T) = 1 + \beta \left(\frac{\lambda_c^s}{\lambda_c} - 1 \right) \quad (5)$$

where β is the sensitivity of the exam and λ_c^s and λ_c are the hazard functions (evaluated at τ) of the sojourn time distributions in the clinical state for a screen-detected and an undetected individual, respectively. Thus if early detection results in a fivefold increase in the mean survival in the clinical state, e.g., from 10 to 50 years for breast

Figure 1 Plot of the unrestricted odds ratio as a function of age for various screening ages and screening exam sensitivities

cancer, which in practice is tantamount to a complete cure, then there will be, *only*, a fivefold increase in the odds ratio. We draw two conclusions from this observation. The first is that relatively modest odd ratios in case-control studies for screening may actually indicate relatively large mortality differences. The second conclusion is that case-control studies result in a significant loss of **power** because even strong clinical effects are associated with odds ratios having a small departure from unity. For example, if a single control is matched to every case, then over 400 pairs are necessary for the power to exceed 50% and almost 1000 pairs are necessary for the power to exceed 80%. Similar results are obtained when more than one control is matched for each case.

The small departure from unity of the odds ratio is explained by the fact that screening is not a regular exposure in the context of case-control studies. Screening has no effect on the survival of an unaffected individual or of an affected but undetected individual. The probability of dying, given a history of screening, is the sum of three terms.

The first is the probability of dying conditional on being in S_h at time τ . The second and third terms are the death probabilities conditional on being in S_p at time τ and being either undetected or detected respectively. The first two terms provide no information about the benefit of screening. Only the third term does. However, the first two terms are larger and dominate the third. A similar effect is observed for the probability of living beyond time T with screening. Consequently the odds ratio does not compare the quantities which directly reflect the effect of early diagnosis. A more meaningful comparison would be for individuals who were undetected in S_p at time τ with matched detected individuals. Unfortunately these are unobservables.

Randomized Clinical Trials

General

The RCT is the method of choice for evaluating the benefit of EDPs and several large-scale trials are currently under way [39–41]. RCTs are designed to

4 Early Detection Programs in Medical Care

eliminate the biases associated with **observational studies**. A typical early detection randomized trial will have a control and a study group. Individuals in the control group receive usual medical care, whereas individuals in the study group will be subject to one or more screening tests. Early detection clinical trials differ from therapeutic trials in that the power is affected by: (a) the number of exams; (b) the time between exams; and (c) the ages at which exams will be given. These design options do not exist in therapeutic trials. Furthermore, long-term follow-up may result in a reduction of power. This feature arises because cases diagnosed in the study group, after the last scheduled examination, may either be those that were evaluated as false negatives or cases that did not have disease at the last examination. It is not possible to distinguish between them. As a result, all deaths are included in the mortality comparisons in order to have an unbiased comparison. A relatively short follow-up time may not have enough deaths to have adequate power. A long follow-up time leads to an increase in the number of diagnosed cases not present at the last scheduled examination. This dilution will result in reduced power. This dilution and the resulting reduction in power are not true for therapeutic trials having a long follow-up time. Another consideration in planning early detection trials is the choice of the target population. In therapeutic trials, all eligible subjects have disease, whereas in early detection trials, subjects do not have disease. However subjects may be incident with disease at a later time. Thus the choice of the target population for the early detection trial is important [42]. A low-risk population may require a very large number of subjects to achieve adequate power.

Analysis

The theoretical foundation for evaluating the benefit of EDPs using RCTs is given in [43]. Their model can be used to investigate various design options such as the number of exams, the optimal spacing between exams, and the length of the follow-up time. Assume that at time τ_0 individuals are registered and randomized into a control and a study group. The study group is offered examinations for the early detection of disease at times $\tau_1 < \tau_2 < \dots < \tau_n$. The i th screening subinterval is denoted by $[\tau_{i-1}, \tau_i)$ for $i = 1, \dots, n$. An individual entering S_p during the i th interval is referred to as an i th-generation individual.

The argument T refers to the chronological time of follow-up; i.e. the total follow-up time is $(T - \tau_0)$.

The probability model calculates the cumulative probability of death for both the control and the study groups under a variety of experimental designs. The cumulative probabilities of death are denoted by $\theta_c(T)$ and $\theta_s(T)$ for the control and the study groups respectively. These probabilities are estimated by $\hat{\theta}_i(T)$, $i = c, s$. The estimators are assumed to follow, in large samples, a normal distribution with mean $\theta_i(T)$ and variance σ_i^2/n_i where n_i is the number of subjects assigned to each group and

$$\sigma_i^2 = \theta_i(T)(1 - \theta_i(T)) \quad (6)$$

The test statistic for testing the equality of these proportions is $Z(T)$ defined by

$$Z(T) = \frac{\sqrt{n} [\hat{\theta}_c(T) - \hat{\theta}_s(T)]}{\sqrt{\hat{\sigma}_c^2 + \hat{\sigma}_s^2}} \quad (7)$$

the large sample power of a one-side α -level test is

$$1 - \Phi [z_{1-\alpha} - \sqrt{n}\delta(T)] \quad (8)$$

where

$$\delta(T) = \frac{\theta_c(T) - \theta_s(T)}{\sqrt{\sigma_c^2 + \sigma_s^2}} \quad (9)$$

and Φ is the standard **normal distribution** function with $\Phi(z_{1-\alpha}) = 1 - \alpha$. The power for detecting a benefit, given by equation (8) is a function of the design parameter of the trial and the sensitivity of the examinations as well as the probability model describing the natural history of disease.

Numerical Examples

We start by investigating the power of a trial comparing: (a) two different schedules (two and four exams), (b) varying the time between exams (1–5 years), and (c) varying the time of the follow-up period (5, 10, 15, optimal in years) for sample sizes of 25 000 in each group. Figure 2(a,b) depict the power calculations for a one-sided level 0.05 test.

The numbers shown on the top curves are the required follow-up years in order to reach the maximum power. The fractions in the figures indicate the proportion of participants receiving all scheduled exams. The calculations show that the greater

Figure 2 Power calculations for a one-sided level of 0.05 test with $n = 25\,000$ in each group showing relationship with time between exams and follow-up times; (a) and (b) depict results for two and four exams

the interval between examinations, the greater the power, provided the follow-up time is long enough to achieve optimal power. However, larger intervals between examinations require a longer follow-up to reach maximal power. Inadequate follow-up time will result in reduced power with longer intervals between examinations.

There is a trade-off between the number of examinations, time between examinations and optimal follow-up times. For example 80% power can be achieved with a **sample size** of $n = 25\,000$ with four exams spaced 2 years apart, provided the follow-up time is 10 years. Increasing the sample size to $n = 50\,000$ will achieve the same power with two exams spaced 2 years apart or three exams spaced 1 year apart with follow-up times of 7–8 or 5–6 years respectively. Larger number of patients results in a reduction of required follow-up time. Many other features of trial design may be similarly evaluated for more details, see [43].

Experimental Design Issues

The classical clinical design, in which there is a

control and a study group, is an ideal way of planning early detection trials. However, since entry into a clinical trial requires subject consent, there may be resistance in consenting to enter a study in which there is the possibility of being assigned to a control group which has no benefit to the individual. For this reason, other experimental designs have been used to evaluate the benefit of the early detection of breast cancer [44–46]. They have some advantages over a classical design in that subjects in a control group may benefit by participating in the study. We refer to the two experimental designs as the *up-front designs* (UFDs) and *close-out designs* (CODs), see [47] and the references therein. The UFD consists of offering an initial exam to all participants. Then they can be randomized to a usual care group or a screening group. If the outcome of the initial examination is included in the analysis, then the study can answer the question of the benefit of an additional screening program after an initial examination. If the analysis excludes all the cases diagnosed at the initial examination, then the analysis evaluates the benefit of a screening program after elimination of the prevalent

cases. These prevalent cases are most likely to be affected by length bias sampling and consequently will tend to have less aggressive disease and live longer. The COD consists of randomizing subjects to usual care and a screened group. However, the usual care group receives an examination which coincides with the last examination in the control group. The COD suffers from a possible bias. This bias arises because the probability of being in the preclinical state at the close-out exam is higher for the control group relative to the study group; i.e. cases in the study group, which potentially could be present at the last exam, may have been diagnosed on earlier exams and hence removed from the population. As a result there is a higher expected number of false negative cases in the control group when given the close-out exam. Both the UFD and the COD have lower power compared to the classical design.

Case–Control Studies

Introduction

Case–control studies are one of the most powerful and widely used study designs in epidemiology and medical research. They are used to investigate the influence of various risk factors, or exposures, on the development of disease. Case–control studies are conducted by sampling a group of individuals with disease called *cases* and a group of disease-free individuals called *controls* and comparing them with respect to the exposure studied. Note that the comparison is retrospective and conditional on the disease status. Any risk factor or disease may be studied with this methodology. For example a study to investigate the effect of smoking on bladder cancer would sample a group of individuals diagnosed with bladder cancer and a disease-free control group and compare smoking histories between the two groups.

Case–control studies are widely used because they are logistically simpler to carry out and are often more cost effective and time efficient than the competing study designs, namely, cohort studies and cross-sectional studies. In a cohort study a large number of individuals are followed over time and their evolving disease status conditional on their exposure is recorded and compared. Cross-sectional studies, or surveys, record the joint occurrence of disease and risk factors at a specific point in time. Moreover, case–control studies are the only feasible option for studying rare diseases because other designs would require very large sample sizes. It is important to note that major breakthroughs in medical research were achieved using case–control methodology. A notable example is the discovery of the relationship between smoking and lung cancer published by the Surgeon General in 1968 [1]. An extensive literature review [2, 3] showed that similar conclusions were reached by randomized controlled **clinical trials**, the gold standard in medical research, cohort studies and most importantly case–control studies. These investigations further strengthened the validity of case–control studies.

Sampling: The Selection of Cases and Controls

Theoretically, the cases and the controls are a random sample drawn from a hypothetical population of diseased and healthy individuals, respectively. Clearly, valid inferences from case–control studies require that the populations of cases and controls be carefully defined and appropriately sampled.

Case selection (see [4] and [5]), starts by defining the disease under study. Too broad or too narrow a definition should be avoided. Furthermore specific inclusion and exclusion criteria should be adopted to further specify the study population. It is also important to decide if prevalent or incident cases are to be studied. The importance of the proper selection of controls cannot be underestimated. The control group should represent the healthy population and be comparable with the case sample [6]. Similar inclusion and exclusion criteria should be used. Care should be taken to avoid selecting a control who has a disease related to the exposure. For example, choosing individuals after myocardial infarction (MI) as a control group for studying the relationship between smoking and lung cancer will tend to underestimate the risk of smoking because smoking is also a risk factor for MI. Therefore it is more common in MI patients relative to the general population. This type of **bias** can be avoided by selecting a heterogeneous control group, and by comparing several control groups. Controls may also be chosen from among family members, coworkers, or neighbors of the cases. For an extensive discussion on the selection of controls see [7–9]. It is common in practice to match cases and controls [10]. The matching may be at the individual level or the group level where it is called *frequency matching*. The goal of matching is to automatically adjust for confounders, i.e., covariates associated with the disease, most commonly age and sex. However, since the matching covariates may be associated with the exposure **covariate**, matching does not preclude the need for confounding adjustments.

Data Analysis: Basic Models and Methods

The data from a generic case–control study can be displayed in 2×2 table as illustrated in Table 1. The

2 Case-Control Studies

Table 1 Case-control basic data representation^(a)

(a)		
	Case	Control
Exposure	A	B
No exposure	C	D
(b)		
	Esophageal cancer (+)	Esophageal cancer (−)
Smoke (+)	182	533
Smoke (−)	9	255

^(a)In this table we present the basic data representation of the case-control study. The table is a 2×2 table with columns representing the cases/control status, while the rows represent the exposure/no exposure status. Table 1(b) gives a numerical example from a case-control study designed to study the association of esophageal cancer with smoking. For more details see [11]

column (or row) variable represents the disease status and the row (or column) variable is the exposure status.

Let Y be the random variable denoting the disease status, i.e., $Y = 1$ for cases and $Y = 0$ for controls. Let X be the random variable denoting the exposure, with $X = 1$ if exposed and $X = 0$ otherwise. Historically [12], the observation that the prospective odds ratio, which is the parameter of interest, is identical to the retrospective odds ratio, which is the quantity we actually observe, was a key factor in the development of case-control methodology. Formally we have

$$\frac{\Pr(Y = 1|X = 1) \Pr(Y = 0|X = 0)}{\Pr(Y = 0|X = 1) \Pr(Y = 1|X = 0)} = \frac{\Pr(X = 1|Y = 1) \Pr(X = 0|Y = 0)}{\Pr(X = 0|Y = 1) \Pr(X = 1|Y = 0)} \quad (1)$$

where the left-hand side of equation (1) is the prospective odds ratio and the right-hand side is the retrospective odds ratio. Additionally when the disease is rare the odds ratio is close to the relative risk $\Pr(Y = 1|X = 1)/\Pr(Y = 0|X = 1)$. The odds ratio is also called the *cross-product ratio* because it can be calculated directly from the 2×2 table as

$$OR = \frac{AD}{BC} \quad (2)$$

In the example given in Table 1(b) the $OR = (182 \times 255)/(533 \times 9) = 9.6$. Note that an odds ratio of unity indicates that there is no relationship between the exposure and the disease. An odds ratio of 9.6 indicates a very strong relationship. Formally we are interested in testing the hypothesis $H_0 : OR = 1$ versus $H_1 : OR \neq 1$. A test statistic based on the log-odds ratio is often used and its large sample, **normal distribution** is obtained using the δ method. Thus

$$\sqrt{n} [\log(\widehat{OR}) - \log(OR)] \longrightarrow^d N(0, V)$$

where $\widehat{OR}$ is the estimated odds ratio, OR is the true odds ratio, $n = A + B + C + D$ is the **sample size**, and V is the variance of the standardized difference. It can be estimated by $\widehat{V} = 1/A + 1/B + 1/C + 1/D$. For a rigorous development see [13]. In our example $\widehat{V} = 0.24$, and $n = 80$, so a simple standard calculation leads us to a significant p value < 0.001 . A formula for the **confidence interval** for the log-odds ratio is given by

$$\log(\widehat{OR}) \pm Z_{1-\frac{\alpha}{2}} \sqrt{\frac{\widehat{V}}{n}}$$

exponentiating both sides we recover the confidence interval for the odds ratio.

In a widely cited paper Mantel and Haenszel [14] showed how to analyze a sequence of K , 2×2 tables with a common odds ratio. Such data is common after stratification over a confounder variable. Letting A_i , B_i , C_i , and D_i represent the observed cell frequencies in the i th table, the Mantel-Haenszel statistic is

$$\widehat{OR}_{MH} = \frac{\sum_{i=1}^K A_i D_i}{\sum_{i=1}^K B_i C_i} \quad (3)$$

The Mantel-Haenszel statistic is unbiased and consistent even when the observations within strata are dependent and the binomial model fails [15, 16]. Its asymptotic distribution was obtained in two different settings; (a) many small 2×2 tables [17]; and (b) a few large 2×2 tables [18].

A more popular and general approach to the analysis of case-control studies is the logistic regression model which enables researchers to model and

Table 2 Matched case-control data representation^(a)

(a)			
		Cases exposed to the risk factor?	
Control exposed to the risk factor?		Yes	No
	Yes	A'	B'
	No	C'	D'
(b)			
		Cases exposed to the risk factor?	
Control exposed to the risk factor?		Yes	No
	Yes	4	1
	No	6	5

^(a) This table presents data from a matched case-control study for investigating the effect of consumption of specific type (sliced Saxony) ham on a *Salmonella* outbreak in Manhattan (unpublished report <http://staff.pubhealth.ku.dk/~bxc/Epi.2006/slides-cc.pdf>)

analyze the occurrence of disease as a function of categorical and continuous covariates. A major appeal of this model is that a prospective logistic regression model, with continuous or discrete covariates, may be fitted using retrospective data [19]. This discovery further popularized the use of logistic regression models which are currently the main tool in the analysis of a wide variety of case-control designs. The logistic regression model assumes that the probability of disease as a function of the risk factors and other covariates is given by the equation

$$\Pr(Y = 1|X = x, Z = z) = \frac{\exp(\alpha + \beta^T x + \gamma^T z)}{1 + \exp(\alpha + \beta^T x + \gamma^T z)} \quad (4)$$

The parameter α quantifies the baseline risk, β quantifies the direction and strength of the relationship between the exposures and the disease, and γ models the effects of confounders z which are simply covariates in the model. Note that the exposure x may be continuous or discrete, univariate or multivariate. The logistic model is easy to fit and to interpret. In fact the regression parameters β and γ are nothing but the log-odds ratios associated with effects of the exposure(s) and confounder(s). Inferential procedures, that is, **hypothesis testing** and confidence intervals are well developed and statistical software easily accessible [20]. Logistic regression models also

allow for easy incorporation of matching, a common feature in case-control studies. The idea is to view each case and its matching control(s) as consisting of a single strata characterized by a unique intercept α_i in equation (4) as in [21] or [22].

If no confounders are present, matched case-control studies may be analyzed using a 2×2 table such as Table 2(a,b).

Matched pairs with similar exposure are called *concordant*, otherwise they are called *discordant*. The discordant pairs are of principal interest. If there is no relationship between the exposure and the disease, then the probability of observing a discordant matched pair would be $1/2$. More formally we would test the hypothesis $H_0 : \phi = 1/2$ versus $H_1 : \phi \neq 1/2$ where ϕ is the probability of observing a discordant pair estimated by $\hat{\phi} = B'/(B' + C')$. A test based on the statistic

$$\frac{B' - C'}{\sqrt{B' + C'}} \longrightarrow^d N(0, 1)$$

is a common choice. This testing procedure is referred to as *McNemar's test*. The odds ratio is given by $OR = \phi/(1 - \phi)$. Note that for small samples, as in Table 2(b), an exact analysis can be conducted. Under the null hypothesis, B' given $B' + C'$ follows a binomial distribution $Bin(1/2, B' + C')$ and testing is easily conducted; the p value here is 0.0625. Alternatively conditional logistic regression may be used [13, 22]. When more than one control is

matched, the Mantel–Haenszel statistic may be used earlier [23, 24].

Finally we note that more flexible, semiparametric models [25–28] have been fit to case–control data. The advantage of these models is that they make few assumptions regarding the relationship between covariates and outcome. Unfortunately the semiparametric approach does not easily lend itself to statistical tests for evaluating the effect of covariates on the risk of disease.

Variations on the Classical Case–Control Design

Many variations on the basic case–control study design are available. In this section we provide a brief overview and description of some of the options. We start with two variations on the classical design. Hospital-based case–control studies are studies in which both the cases and the controls are sampled from among patients of one or several hospitals. This design has many benefits; it is logistically simple to carry out, the data is usually of high quality, with less recall and nonresponse bias. Its major drawback is that the control population may be different, in important aspects which are difficult to account for, from the at risk population. On the other hand, in population-based case–control studies, the cases and the controls represent the risk population well. However the source population at risk for the disease, also called the *study base*, must be well defined, and randomly sampled. In addition most of the benefits associated with hospital-based studies do not exist [7, 29].

We now mention several designs that extend the classical case–control study. The case–cohort design is a design that combines the strengths of a cohort study with that of a case–control study. At the start of a cohort study a subsample of it is randomly selected. Risk factors for this subsample are carefully measured and monitored. At the end of the follow-up time this subsample is compared to all the cases occurring during the study [30, 31]. Another closely related design is the nested case–control design, which is also cohort based. In this design, the cases are the events in the cohort and the controls are randomly sampled individuals from the cohort who are at risk at the time of each event [32]. Both designs

are useful for studying a rare disease and evaluating the influence of exposures that are either hard or expensive to measure. The sequential case–control study involves repeated hypothesis testing performed as the data accumulates. This is usually done when a new risk factor is discovered and examined and the data accumulates serially [33, 34]. The two-phase case–control study, also referred to as the *double sampling case–control study*, is another design worth mentioning [35, 36]. In this design one first samples a large group of cases and controls from the general population. In a second phase of sampling one samples these groups. The second phase of sampling is differential. For example, one may sample exposed individuals with higher probability than nonexposed. Recently, family-based case–control studies have gained popularity. In these studies, the families of cases are sampled and compared with families of controls. These studies are used to assess the role of genetic factors and their interaction with environmental factors in causing disease [37].

Limitations of Case–Control Studies

Case–control studies are versatile and an increasingly important tool in biomedical research. Nevertheless, despite their usefulness, case–control studies are not foolproof and should always be conducted with care to avoid common biases. Bias is defined as a systemic distortion that leads to an estimated odds ratio that is consistently different from the true odds ratio. Case–control studies are subject to a variety of biases; the most important ones are selection bias, nonresponse bias, and information bias. Measurement error in the exposure variables and unaccounted for confounders may also lead to bias. It is advisable to identify all possible sources of bias in the design phase [38]. Selection bias arises when the cases and controls are not representative of their parent populations. In such situations, the distribution of the exposure in the study population is different from its distribution in the reference population. This bias can be avoided by carefully defining the study base from which cases and controls are sampled [39]. Selection bias may also arise owing to high nonresponse rates among either cases but more commonly in the control population. Care should be taken for the response rate to be as high as possible. In situations where that goal is not

achieved, data analysis should be made to make sure that the responders and nonresponders share the same demographic characteristics. Information bias exists when the exposure is reported or measured differently among cases and controls. Recall bias, the bias associated with reporting on health history, in population selected controls is an example of this type of bias [40]. These biases are forms of the general measurement error problem.

In addition to the aforementioned difficulties, which can be addressed with careful planning, there are some inherent problems associated with case-control studies. Most importantly case-control studies are observational and not randomized studies. Therefore a positive relationship between an exposure and disease cannot be considered to be a causal relationship. This problem is further complicated by the fact that it is never known whether all confounders have been accounted for. Another important drawback of case control studies is that they do not allow for the **estimation** of the overall risk or prevalence of the disease. There are also many subtle statistical issues, for some interesting examples from family studies and from screening studies see [41, 42].

ORI DAVIDOV AND AMIR HERMAN

Patient Opinion Measures

Introduction

In healthcare a wide range of patient opinion measures has been developed. Most of these measures are questionnaires, which may be provided to patients by (e-)mail, in face-to-face or telephone contacts, or through the Internet. Many measures have focused on either patient reported symptoms and health-related quality of life, or on patient opinions on healthcare – the latter is the focus of this contribution. Patient opinion measures have been used in scientific research for a long time, but only in recent decades they are increasingly used for quality improvement, accreditation of healthcare providers, and public reporting on quality of care providers. In these applications the users are not necessarily researchers, but citizens, patients, healthcare providers, health authorities, and policy makers. In many countries a market of patient survey research has developed in recent years and users of patient opinion measures have to choose from a range of competing measures.

From a methodological and statistical perspective, there is nothing unique in the validation or application of patient opinion measures compared to other measures. More recent developments in questionnaire methodology, such as computer-assisted interviewing and item–response theory, have not yet reached the field of patient opinion measures. In fact, many patient opinion measures, which are currently used in applications, have hardly been validated. A few measures have been validated reasonably, but it can be observed that methodological issues related to their application of the instrument tend to be ignored [1]. This can seriously **bias** the results, also if the measure itself was carefully developed and validated. This contribution aims to provide an overview of some statistical issues in the application of patient opinion measures. It uses the Europep instrument to illustrate the points made [2] (Box 1).

Methods

Sampling Participants

An appropriate sampling procedure is crucial for the validity of any population-based study. This requires,

among others, a clear definition of the sampling frame (from which cases are sampled) and a sampling procedure that avoids bias (ideally, random sampling). Bias caused by the sampling procedure cannot be compensated for by larger sample sizes. A small but appropriately sampled study population may be preferable to a large but biased sample. New statistical methods for handling biased samples (e.g., sampling participants through the Internet) may widen the opportunities in the future. The Europep instrument was not made for one particular sampling procedure. Many users have consecutively recruited patients among visitors of a general practice, but others have randomly sampled patients from practice registers or population registers.

Response rate can be defined as the number of completed questionnaires divided by the total of questionnaires that reached the target population. A low response rate could induce selection bias. Many studies with the Europep instrument have achieved response rates of 70% or higher. It is recommended to strive for a response rate of at least 60% in using the instrument. Sending reminders increases the response rate by about 10% and repeated mailing of the questionnaire was only marginally more effective than a simple postcard reminder [3]. In many situations it is necessary to use reminders to achieve acceptable response rates. It is recommended to interpret results carefully if the response rate is low (e.g., lower than 60%). While the results may still be valuable for educational feedback and scientific research, they are probably less useful for accreditation and public reporting.

It is difficult to provide recommendations on absolute figures for the **sample size** in studies, which use patient opinion measures. Inclusion of more patients increases the **power** of the study and results in more accurate estimations (smaller **confidence intervals**). If figures are presented for specific practices or practitioners, it should be taken into account that the data are clustered. Statistical advice on appropriate power calculations may be needed. Some studies have suggested that a minimum of 60 respondents are needed per practice/practitioner to allow for reliable figures at the level of practice/practitioner [4]. Lower numbers may be acceptable in educational feedback or scientific research, depending on the research question.

2 Patient Opinion Measures

Box 1 Construction and revision of the Europep questionnaire

The Europep instrument was developed by an international consortium of researchers and family physicians in the years 1995–1998. It was developed from the beginning as an international instrument for patient evaluations of general practice, using rigorous translation and validation procedures. We aimed at use for educational purposes in general practices and regions as well as nationwide surveys and international comparisons. A series of studies were performed for its development, including an international study on patient priorities and studies to examine protoversions of the questionnaire. The questionnaire is focused on evaluations of specific aspects of general practice (not: priorities, wishes, reports, experiences, satisfaction, utilities, etc.). It comprises 23 items, which use a five-point scale (poor–excellent). Explicit criteria were used for the final selection of items, which focused on coverage of domains of general practice, importance to patients, item response, language problems, and discrimination (specific quantitative criteria were formulated). Providing effective feedback on Europep data was not explicitly addressed, but some countries have developed elaborated feedback procedures. More information can be found on www.swisspep.ch/pages/EUROPEP.html.

In 2006, the users of the Europep instrument felt a need to revise and possibly extend the Europep questionnaire. The questionnaire had been used in more than 20 European countries, in some cases on a very large scale (e.g., in Denmark and Switzerland). We sought a balance between improving the questionnaire and maintaining a core set of items – needed for comparisons over time. We planned to exclude and revise items on the basis of a systematic process with a group of users of the Europep instrument. The criteria were specified *a priori*: (a) An item would be omitted or revised if there was a serious ambiguity or translation problem in any country, leading to misinterpretations (item interpretation). (b) An item would be omitted or revised if there would be an unexpected response of lower than 30% in more than half of the countries (item response). (c) An item would be omitted or revised if more than 80% of the respondents used only one of the five answering categories in most (>80%) countries (item discrimination). The EPA project data on Europep data (collected in the period 2000–2005) provided data on item response and discrimination (www.ru.nl/topas-europe). Eight rounds of proposals and feedback were done in the group of users over the email, using a cumulative list of interpretation problems and revision proposals. The criteria regarding item response and discrimination did not lead to omission of items, but a range of interpretation problems was identified which led to a number of small revisions. The result was the prototype of the Europep 2006 questionnaire:

What is your assessment of the general practitioner over the last 12 months with respect to:

1. Making you feel you have time during consultation*
2. Showing interest in your personal situation*
3. Making it easy for you to tell him or her about your problem
4. Involving you in decisions about your medical care
5. Listening to you
6. Keeping your records and data confidential
7. Providing quick relief of your symptoms*
8. Helping you to feel well so that you can perform your normal daily activities
9. Thoroughness of the approach to your problems*
10. Physical examination of you
11. Offering you services for preventing diseases (e.g., screening, health checks, immunizations)
12. Explaining the purpose of examinations, tests, and treatments*
13. Telling you enough about your symptoms and/or illness*
14. Helping you deal with emotions related to your health status*
15. Helping understand why it is important to follow the GP's advice*
16. Knowing what has been done or told during previous contacts in the practice*
17. Preparing you for what to expect from specialists, hospital care, or other care providers*

Box 1 continued

What is your assessment of the general practice over the last 12 months with respect to:

18. The helpfulness of the practice staff (other than the doctor) to you*
19. Getting an appointment to suit you?
20. Getting through to the practice on telephone?
21. Being able to talk to the general practitioner on the telephone*
22. Waiting time in the waiting room?
23. Providing quick services for urgent health problems?

*Revised items

Handling of Items

Health services research is a multidisciplinary research domain, which borrows from clinical epidemiology and social science methodology. The two traditions do not always take the same approach, which is certainly the case in the handling of questionnaire items. The psychometrics tradition regards items as repeated measurements for an underlying concept, so the scores of correlated items should be aggregated to compose a measure of the underlying concept. It is this aggregated measure, which is most relevant for the study. The clinimetrics tradition, on the other hand, tends to regard items either as independent measures (each item reflects one concept) or as aspects of a known biological process (e.g., symptoms of a disease). In the latter case, items are simply added up without a need for an observed high **correlation** between the item scores. In health services research, often a balance has to be found between the two approaches.

In the Europep instrument each item has been developed to reflect a specific concept, such as “availability of the GP on the telephone” or “time in the consultation”. In other words, different items were not primarily designed as repeated measures for underlying concepts. Therefore, items were presented and interpreted separately. Scales are aggregations of different items, which reflect an underlying concept. While the precise meaning of the individual items gets lost, the advantage of scales is that these are usually more accurate than individual items (smaller confidence intervals). Explorative psychometric analyses of Europep data (principal factor analysis, orthogonal rotation, accepting factors with eigenvalue higher than 1) showed that the Europep instrument contains

two scales: an evaluation of clinical management and an evaluation of practice management.

The following procedure was used in the analysis of Europep data. Reliability analysis was used to verify the internal consistency (Cronbach’s α) on each of the two scales in the Europep instrument. Raw scores were used for analysis; cases with missing values were excluded by list-wise deletion. It was felt that Cronbach’s α should be 0.70 or higher (an arbitrary value); in reality, α ’s were much higher. While different procedures for calculation of scale scores may be acceptable, the following procedure was recommended as a standard for Europep users. Items are dichotomized according to 5 *versus* 1–4 (“excellent *vs* less than excellent”). The category “excellent” is coded 1, while the other valid values (excluding the missing values) are coded 0. Then the mean value of the items in the scale is determined. For this purpose a new variable is defined, which is the mean value of the selected items. The result is a score for each individual, which can be interpreted as the proportion of items, which were assessed as “excellent”.

Missing values are a problem for any study, which cannot be fully solved satisfactorily. Many users of the Europep instrument have regarded the category “do not know/not applicable” as a missing value. This implies that cases with missing values were not included in the presentation of scores on the items. It is recommended to Europep users to use this approach as the standard procedure. In the calculation of scales of the Europep instrument, missing values were handled as follows. Patients are excluded if more than one-third of the items in the scale were missing values (no answers or not applicable/not relevant). **Imputation** of missing values in scales

4 Patient Opinion Measures

(e.g., by mean on the other items in the scale) is not recommended, because this artificially increases the consistency of the scale scores.

Presentation of Findings

For educational purposes little more than presentation of absolute numbers and percentages in each answering category for each item may be needed. For comparison with other providers or patient groups potential confounders should be considered. The most obvious confounder in studies of patient views is patient age, although the absolute size of effect of age is small. It has been found fairly consistently that older patients have more positive views of the care received (for which no evidence-based explanation is available). The impact of other patient characteristics is less consistent and probably small, after adjustment for patient age. In the application of the Europep instrument it is recommended to control for age in comparisons, particularly if they are used for accreditation or public reporting.

Furthermore, it is recommended to present all figures with confidence intervals, certainly if they are used for accreditation or public reporting. In many, if not all, applications data are clustered within practices or practitioners (different patients from the same practice/practitioner are included). This implies that random effects models should be used, for which expert statistical advice is often required. Inappropriate statistics are most likely to overestimate differences and changes, because confidence intervals tend to be wider after correction for clustering. This implies that differences between care providers or changes over time are observed, while these are in fact not significant.

In practical applications, the ultimate goal is to improve quality of care (which may be operationalized in different ways). Despite the enormous number of patient opinion studies, the evidence on its impact on quality of care or patient outcomes is very scarce. A randomized trial showed that providing educational feedback on patient opinions of

general practice was positively received by physicians, but did not lead to observable changes in professional behavior or practice management [5]. The use of patient opinion measures in accreditation and public reporting may be more effective, but research evidence to support this claim is currently not available.

Conclusions

Patient opinion measures need to be validated and used sensibly, like any measure. Some statistical aspects of sampling participants, handling of items, and presentation of findings were discussed in this contribution. The Europep instrument was used throughout the paper to illustrate the points made. Statistical aspects of applying patient opinion measures should be addressed to avoid bias, also if the measure itself was carefully developed and validated.

Clinical Behavior Change

Introduction

Clinical Behavior Change: A Systematic Model for Change

Many patients do not receive optimal care. They do not receive, or receive inappropriately, the care they should have been given according to current guidelines for good clinical practice. Or they receive superfluous care. They are exposed to medical interventions that are no longer indicated because of undesirable side effects or proven lack of effect. Clinical behavior change is directed at improvements in patient care, including adoption of evidence-based medicine guidelines, procedures, technologies, or care programmes. Clinical behavior change may also be directed at removal of undesirable (i.e. unnecessary, harmful, or inefficient) routines and variations in the care provided [1].

The number of quality improvement projects in healthcare is increasing throughout the world. Different approaches to clinical behavior change can be observed, each based on different assumptions and theories of human and organizational behavior. Some focus on internal and others on external influences. Despite the varying orientation, most approaches suggest that implementing change effectively requires a systematic, stepwise process. The following steps can be distinguished [2]:

1. Formulation of a concrete, well-developed, and attainable proposal for change in practice, with clear targets.
2. Analysis of the target group and the setting: what are the problems in care provision, and what factors are stimulating or hampering the process of change?
3. Development or selection of a set of strategies for change: strategies for both the effective dissemination and the effective implementation and maintenance of change.
4. Developing and executing an implementation plan that contains activities, tasks, and a timetable.
5. Evaluation and, if necessary, revision of the plan: continuous monitoring on the basis of indicators for the quality of healthcare that is under study.

Interventions for Clinical Behavior Change

Numerous interventions can be used to improve behavior. The best-evaluated interventions are the professional-oriented interventions such as distribution of educational materials, conferences, local consensus processes, audit and feedback, or reminders. Behavior change in professionals can also indirectly be strived for by patient-oriented strategies, e.g., by direct mailings to middle-aged women alerting them on regular screening for cervix cancer and stimulating them to remind their doctor. Another important category of clinical behavior change interventions is on the level of organizational measures, such as, e.g., changes in medical record systems, the introduction of telemedicine, the introduction of multidisciplinary teams, or revision of professional roles. Less well studied are financial measures aimed at quality improvement, such as, e.g., a performance-based payment, or legal regulation and/or rules such as, e.g., change in medical liability or accreditation measures. A taxonomy for clinical behavior change strategies is available on the website of the Cochrane Collaboration Effective Practice and Organisation of Care Group: www.epoc.uottawa.ca.

Statistical Issues in Research on Clinical Behavior Change

Research on clinical behavior change is the scientific study of methods to promote the systematic uptake of clinical research findings into routine practice and hence, to improve the quality and effectiveness of healthcare. It identifies the behavior of healthcare professionals and healthcare organizations as key sources of variance requiring improved empirical and theoretical understanding before effective interventions can be reliably achieved [3].

Both quantitative and qualitative approaches in **data collection** may play their role in clinical behavior change research. In this chapter we focus on statistical issues in the collection of quantitative data for steps 2 and 5 of the implementation model. In step 2 the gap between current care and the proposal for change in practice should be analyzed, and in step 5 the effect of an implementation strategy on indicators for the desired behavior. The validity of measurements of clinical behavior, clustering effects, and the magnitude of interdoctor variation are important issues. In experimental studies on the effectiveness of implementation strategies, the same statistical issues

2 Clinical Behavior Change

play a role as in each (randomized) controlled trial. Clustering is a specific statistical issue in trials on clinical behavior change, as many studies of clinical behavior change are cluster randomized trials, effecting **power** calculation, and level of analysis. We will briefly discuss these issues, illustrated with examples from a study on the test-ordering behavior of general practitioners (GPs) in the Netherlands.

Methods

The Measurement of Clinical Behavior

An all-inclusive measurement of clinical behavior is usually too complex to be possible, so a limited number of crucial aspects of care should be selected for measurement, such as key recommendations in a clinical guideline or those aspects of care that cause most problems to patients. The key recommendations should be translated into quality indicators. A quality indicator is “a measurable element of practice performance for which there is evidence or consensus that it can be used to assess the quality, and hence change in the quality of care provided” [4]. Quality indicators can refer to structures, processes (interpersonal or clinical), or outcomes of care. Examples are given in Table 1 [4].

There is a long debate on the value of outcome indicators *versus* process and structure indicators. Ideally, indicators refer to the effectiveness and safety of healthcare in terms of health status and other patient outcomes. A problem is that many patient outcomes are influenced by many other factors in addition to the process and structure of healthcare, such as patients’ compliance with treatment, hygiene, and nutrition status. In

many studies, indicators refer to processes of care: clinical procedures, communication, and decision-making processes. These indicators tend to be closely linked to professional performance and organization of care, so they can be interpreted more easily in terms of quality of care. Process indicators may have a low or high degree of specificity. This can be illustrated by different examples of prescription rates, ranging from low to high specificity:

- Number of prescriptions per 1000 patients per professional per year.
- Number of prescriptions of an obsolete drug per 1000 patients per professional per year
- Number of a specific first-choice antibiotic drug per 1000 patients per professional per year.
- Number of a specific first-choice antibiotic drug in the correct doses per 1000 patients per professional per year.

General volume data might be easily accessible in existing computerized data sets and can give important information on variation between professionals. The outcome may become more meaningful by integrating patient data in the denominator of the indicator. This is usually expressed as a proportion; for example: the number of first-choice antibiotic drugs/100 patients diagnosed with the disease for which the antibiotic is indicated/professional/year.

The development and validation of indicators for performance or quality of care is a developing science. Existing methodology could be used, although examples of methodological studies of indicators are as yet scarce. For instance, for aggregation of indicators into mean scores, scale construction methods can be used, such as principal factor analysis. Methods from epidemiological diagnostic studies could be used for assessing indicators, if a gold standard is available. Generalizability analysis can be used for assessing the consistency of indicator scores per practice, institution, or geographic region. This chapter focuses on one aspect of the analysis of indicators, which is the statistical clustering of data on clinical behavior.

Clustering of Clinical Behavior

A fundamental assumption of the standard statistics used to analyze outcome indicators on patient level

Table 1 Different types of quality indicators

Indicators	Measures
Structure indicators	Number of professionals (full-time equivalents) per 1000 patients Special clinic rates
Process indicators	Referral rates Prescription rates Vaccination rates
Outcome indicators	Hospital readmission rates Postoperative wound infections rates Pressure ulcers rates

is that the outcome for an individual patient is completely unrelated to that for any other patient – they are said to be “independent”. This assumption is violated if two patients within any one cluster are more likely to respond in a similar manner on the outcome indicator than two patients from different clusters [5]. For example, the management of patients in a single general practice is more likely to be consistent than management of patients across different general practices. The clustering effect may also play its role on the level of professionals and their scoring on process and structure indicators. Two nurses within a hospital might be more likely to respond in a similar manner to an investigation of adherence to a guideline on pressure ulcer treatment than two nurses from different hospitals. Two GPs working closely together in one practice might be more likely to respond in a similar manner to an investigation of their degree to delegate tasks to practice assistants than two GPs from different practices.

A statistical measure of the extent of clustering is the “intracluster **correlation** coefficient” (ICC) which is based on the relationship of the between-cluster to within-cluster variance [5, 6]. According to Eccles *et al.*, ICCs for measures of the process of care tend to be higher than those for measures of patient based outcomes, and ICCs for measures of the process of care in secondary care settings tend to be higher than those for similar measures in primary care settings. A database of ICCs across a range of activities and settings is available from <http://www.abdn.ac.uk/hsru/epp/cluster.shtml>.

Analysis of Clinical Behavior to Describe the Gap between Optimal and Current Care

A wide range of simple or complex data collection methods may be used and all have their advantages and disadvantages. Examples include the manual or electronic abstraction of data from medical records or from existing databases on certain patient groups, e.g., insurance company data, the (prospective) documentation of activities by care providers or patients, and documentation of activities by an observer. In Box 1 an example is given of an analysis of data derived from regional laboratories describing test-ordering rates of GPs in the Netherlands [7]. The aim of the study was to explore the determinants of interdoctor variation. In a study with 229 GPs in 40 local GP groups^a from five regions, the

test-ordering behavior of the GPs was described, to establish professional-oriented and contextual determinants of inclination of the GPs to order tests. The data had a clear hierarchical structure, with GP groups operating under single regional laboratory facilities (regions) and GPs collaborating within GP groups. The test-ordering behavior of two GPs within the same GP group may be more similar than that of two GPs from different GP groups. The same holds for GP groups within a region being perhaps more similar – due to differences in quality assurance activities of the laboratory facility – than two GP groups randomly chosen from different regions. Therefore, the data were modeled in a

Box 1. An example of analysis of current care practice. Variation in test-ordering behavior of general practitioners (GPs)

Data on 19 laboratory and eight imaging tests ordered by GPs, were collected from existing databases in 5 regional laboratory facilities, and cross sectionally analyzed. In a multivariable multilevel regression analysis, these data were linked with **survey data** on GP characteristics such as knowledge about and attitude towards test ordering, and with data on contextual factors such as practice type or distance to the laboratory facility.

Large interdoctor variations were found with skewed distributions. The total median number of tests per GP per year was 998 (interquartile range 663–1500), with large differences between the regions ($p < 0.001$). The response to the survey was 97%. Three variables appeared to be strongly associated with the numbers of tests ordered. “Individual involvement in developing guidelines” (GP level), and “group practice” and “more than 1 year of experience working with a problem-oriented laboratory order form disseminated by the diagnostic center” (contextual level) were associated with reduced numbers of tests ordered of 27, 18, and 41%, respectively, compared with the reference categories.

three-level multilevel analysis model with GP group and region as the random coefficients. The random

variation due to local GP group level proved to be small and insignificant after three GP group level related variables had been omitted. The intraclass correlation coefficient at the region level was 0.304, meaning that the variation between regions was large compared with the variation within regions, which supports the assumption that variability in test ordering is strongly correlated with a region factor.

Contamination in Experiments of Strategies for Clinical Behavior Change

While it is possible to conduct trials of clinical behavior change strategies that allocate individual patients, this may not always be ideal because of contamination in the control group. An example of contamination is an obstetrician who is given an electronic reminder for folic acid advice for women allocated to the intervention arm and not for women in the control group, which after a short while results in the desired behavior in both groups. The ultimate protection against contamination in a trial is to allocate on the level of clusters instead of patients. This results in a group of obstetricians who are exposed to the reminder in all their patient contacts *versus* a group of obstetricians in the control arm who are not exposed at all to the reminder. The disadvantage is that allocation at the level of the professional has lower statistical power than a patient-randomized trial of equivalent size [5].

How to Deal with Clustering in Experiments of Strategies for Clinical Behavior Change

Cluster randomized trials can help to diminish the disadvantage of lower statistical power. In such trials the **randomization** is at one level (professional or organization) and data collection is at a different level (patient) [8]. There are three general approaches to the analysis of cluster randomized trials: analysis at the cluster level; the adjustment of standard tests; and advanced statistical techniques using data recorded at both the individual and cluster levels [8]. Cluster level analyses use the cluster as the unit of randomization and analysis. A summary statistic (e.g., mean, proportion) is computed for each cluster and as each cluster provides only one data point, the data can be considered to be independent, allowing standard statistical tests to be

used. Patient-level analyses can be undertaken using adjustments to simple statistical tests to account for the clustering effect. However this approach does not allow adjustment for patient or practice characteristics. Advances in the development and use of new modeling techniques to incorporate patient-level data allow the inherent correlation within clusters to be modeled explicitly, and thus a “correct” model can be obtained. These methods can incorporate the hierarchical nature of the data into the analysis. For example, in a primary care setting, we may have patients (level 1) treated by a GP (level 2) nested within practices (level 3) and may have covariates measured at the patient level (e.g., patient age or gender), the GP level (e.g., gender, time in practice), and at the practice level (e.g., practice size) [6]. In Box 2 an example is given of an experimental evaluation of a strategy to improve test-ordering behavior of the GPs [9]. In this study, a multifaceted strategy using guidelines, feedback, and social interaction resulted in modest improvements in test ordering by GPs. The strategy consisted of individualized feedback, education in the GP group on guidelines and peer group discussion based on mutual comparison of test-ordering behavior. To account for clustering within local groups, a three-level model was used with the local group as level 3, individual GPs as level 2, and the total number of tests per 6 months per GP as level 1. In multilevel analysis the point estimate and standard deviation were about the same as in the analysis of **covariance** at the individual level and therefore no correction for local groups was needed even though the ICC for the local GP groups was about 0.10.

Sample sizes for cluster randomized trials need to be inflated to adjust for clustering. Both the ICC and the cluster size influence the inflation required; the sample-size inflation can be considerable, especially if the average cluster size is large. The extra numbers of patients required can be achieved by increasing either the number of clusters in the study – the more efficient method [10] – or the number of patients per cluster. In general, little additional power is gained from increasing the number of patients per cluster above 50. Researchers often have to trade-off the logistic difficulties and costs associated with recruitment of extra clusters against those associated with increasing the number of patients per cluster [6]. A power-calculation

Box 2. An example of evaluation of a strategy for clinical behavior change; the effects of a multifaceted strategy aimed at improving the performance of test-ordering behavior of the GP

The strategy was executed among 26 local GP groups including 174 GPs in five regions in the Netherlands. It was evaluated in a cluster randomized controlled trial with a balanced, **incomplete block** design and randomization at group level. Thirteen GP groups underwent the strategy for three clinical problems (arm A; tests for cardiovascular topics, upper and lower abdominal complaints), while 13 other groups underwent the strategy for three other clinical problems (arm B; tests for chronic obstructive pulmonary disease and asthma, general complaints like fatigue, degenerative joint complaints). Each arm acted as a control for the other. During the 6 months of intervention (Jan–June 1999), physicians discussed three consecutive, personal feedback reports in three small group meetings, related them to three evidence-based clinical guidelines, and made plans for change. According to existing national, evidence-based guidelines, a decrease in the total numbers of tests ordered per clinical problem was considered a quality improvement. Baseline data were from July to December 1998, follow-up data were from July to December 1999. All effects were analyzed with analysis of covariance using the number of tests during the follow-up period as the dependent variable and the number of tests at baseline and the region, which appeared to be an important variable, as independent variable.

For clinical problems allocated to arm A, the mean total number of requested tests per 6 months per physician was reduced from baseline to follow-up by 12% among physicians in the arm A intervention, but was unchanged in the arm B control ($P = 0.01$). For clinical problems allocated to arm B, the mean total number of requested tests per 6 months per physician was reduced from baseline to follow-up by 8% among physicians in the arm B intervention, and by 3% in the arm A control ($P = 0.22$).

programme for cluster randomized trials is available at <http://www.abdn.ac.uk/hsru/epp/cluster.shtml>.

Discussion

In this chapter we have stressed the importance of a systematic approach in clinical behavior change research and highlighted the issue of statistical clustering of data on clinical behavior. Considerations are given for the choice of the outcome measure. Careful analysis of clinical behavior to describe the gap between optimal and current care or to find determinants of interdoctor variation may result in useful insights leading to keys for quality improvement. Statistical issues in trials of clinical behavior change research do not differ widely from controlled trials on other topics, but attention has to be paid to the issue of clustering of patients or clinical behavior.

New modeling techniques can incorporate the hierarchical nature of the data into the analysis and at the same time covariates measured at the patient level can be incorporated. Which of the methods

is better to use is still a topic of debate [6]. The most appropriate analysis option will depend on a number of factors including the research question; the unit of inference; the study design; whether the researchers wish to adjust for other relevant variables at the individual or cluster level (covariates); the type and distribution of outcome measure; the number of clusters randomized; the size of cluster and variability of cluster size; and statistical resources available in the research team [6].

AND MICHEL WENSING

Quality in Critical Care Medicine

Introduction

Critical care medicine is a growing element of modern hospital medicine. Critically ill patients consume about of 20% of hospital budgets and approximately 0.8% of the GNP in the United States and 0.2% in Canada [1]. It is therefore a very expensive part of hospital medicine.

Intensive care units (ICUs) can be structured in different ways: according to patient population (such as surgical *vs* medical, neuro, and burns) and according to organization of patient care (open *vs* closed units).

The recent interest in quality improvement in healthcare has not skipped the ICU environment and there are many opportunities to improve on the delivery of critical care provided in ICUs. To describe these, a brief look at the current issues that are problematic in caring for critically ill patients is needed.

The patients in the ICU are frequently the most complex patients in the hospital. These are the patients who require intensive monitoring and often complex and multiple therapeutic interventions. Many drug prescriptions are provided to these patients on a daily basis and this has been shown to be a ground for drug errors, which can lead to adverse patient outcomes [2].

Many factors impact the processes and therefore the outcomes of patients in the ICU. The physical design and equipment available, the organizational workflow of various medical services, and the interactions between the different members of the ICU team: physicians, nurses, pharmacists, physiotherapists, respiratory therapists, and social workers are all critical to achieve optimal outcome, and their availability as well as the communication between them all have a critical impact on the function of the ICU.

Determinants of Quality

A look at quality in ICUs requires observation of a number of components. Design, both physical and organizational setup, of the ICU can impact the

process and clinical outcome. Process, includes the approach to patients with regard to using protocols, workflow of organization, and guidelines, and outcome primarily deals with the clinical outcome of patients admitted to the ICU, but also pertains to other markers of significance such as cost, length of stay, and resource use. An important component of outcome is patient and family satisfaction with the process in the ICU. An admission to intensive care is frequently a very dramatic episode in a person's life and the impact it has on the patient and family can and should be addressed, measured, and improved upon.

Physical design of the ICU can have significant effect on the workflow, on personal and patient satisfaction, and therefore on clinical outcome. Poorly designed work stations can lead to increased rate of medical errors, may impair communication, and increase the risk for nosocomial infections.

ICU Structure: Open *versus* Closed

Many ICUs are organized in an "open" manner. This means that the patients are admitted to the ICU by a primary physician who continues to carry the responsibility for all aspects of the patients' stay in the ICU. This implies that although consultants are used, the treatment of different patients may be quite diverse with some difficulty in implementing routines and protocols for the different clinical issues that may arise. "Closed" units have a primary ICU team that directs care of the patients when they are admitted to the ICU. These clinicians are "dedicated intensivists" and spend a major part of their time in caring for critically ill patients. Studies have shown differences in outcomes between closed and open units with an advantage to a closed unit [3].

The clinical process in the ICU spans the encounter with the patient from the decision on admission to the ICU and the therapy afforded to patients even before they are admitted to the ICU. Rivers and colleagues have shown that early goal directed therapy in patients with severe infections can dramatically reduce mortality. They applied this approach to critically ill patients who required intensive care while they were still in the emergency room waiting for admission to the ICU [4, 5].

Staffing

Staffing of the ICU by nurses affects the quality of healthcare delivered to the patients and to families. This has been shown in the effect of nursing ratio on nosocomial infections (infections acquired in the ICU). A low nursing ratio led to a 30% increase in nosocomial infections. These infections led to increased morbidity and mortality [6]. Other studies have also shown that staffing by nurses can impact various outcome parameters. The availability of other paramedical personnel in the ICU, such as pharmacists, can also lead to improved quality and cost reduction.

Medical Error and Error Prevention

Medical errors are responsible for a great number of adverse events in critically ill patients. A model of medical error was described by Leape [7]. Most errors are due to a system failure rather than a failure by a particular individual. Errors are difficult to reduce because of the complexity of medical systems, and also because healthcare professionals are often reluctant to report and disclose the details of medical errors because of concern of punishment. A comprehensive approach to reducing medical errors requires an open and blame-free attitude. This will allow reporting of incidents that can be collected and studied, and with the use of information from large data-bases allow conclusions as to root causes of errors.

Errors are often divided into those due to faulty planning and those due to faulty execution, and they can be errors of commission or errors of omission. The usual model for medical errors describes the “Swiss cheese model”. The theory behind this model is that all processes have inherent faults in them, the so-called holes, which do not lead to error because each process is composed of many components and the faults in each component need to be aligned to lead to an actual error. To minimize or eliminate errors, efforts must be made to investigate possible errors and near misses, strive to reduce the holes in the system, and allow for backup mechanisms that will decrease the likelihood of a number of faults occurring in the same process in a manner that can lead to error.

Among the various mechanisms designed to reduce errors are the use of computerized systems and

the implementation of appropriate communications protocols between staff. Other important issues are the empowerment of all clinical personnel as well as patients and their families to question a process or a decision and to alert and even abort a process if potential error is suspected.

Evidence-Based Medicine

Many activities and clinical procedures in the ICU are based on personal experience and anecdotal information. There is now a growing body of evidence regarding the best policies and procedures that should be used to achieve the best outcome in critically ill patients. This information can direct the appropriate therapy with regard to ventilatory management in patients with acute respiratory distress syndrome (ARDS) [8], weaning from mechanical ventilation [9], the initial approach to hemodynamic management of patients in septic shock [4], and metabolic management of patients with regard to the control of glucose levels and insulin administration [10].

Despite the fact that these issues have significant data to support their implementation, studies have shown that clinicians are not always ready to adopt evidence-based therapies and their implementation is not universal by any means. For example, following the publication of the National Institutes of Health (NIH) study that showed that reduced tidal volumes can decrease mortality in mechanically ventilated patients with ARDS, there was a consistent but moderate application of this information in the treatment of patients with ARDS as seen in a study in a number of ICUs in the New England area [11].

Even established and standard therapies that are uniformly considered to be part of routine care are not universally complied with. Pronovost *et al.* measured compliance with routine procedures such as adequate sedation, elevation of the head of the bed, deep venous thrombosis (DVT) prophylaxis, and appropriate use of blood transfusion in the ICUs of 13 teaching and community hospitals. They found the compliance for these approaches to be between 33 and 89% [12].

It should be noted that although these and many other interventions have substantial levels of evidence that indicate the appropriate therapy to be followed when a number of choices are available, the treatment of critically ill patients is very complex and chaotic.

The physiologic response to illness and to therapy is very diverse and general approaches may not always be able to indicate the correct or optimal strategy in each and every case. Probably the most significant determinant of outcome in the treatment of complex critically ill patients is the management by an experienced, dedicated clinician.

Guidelines, Protocols, and Bundles

Although the importance of an experienced intensivist cannot be overstated, it is not possible to provide this service to every critically ill patient. This amplifies the importance of treatment provided using the best available clinical knowledge by following protocols and guidelines. Protocols can provide a framework and suggest the optimal diagnostic and therapeutic interventions required to handle various situations.

A new concept regarding the application of best practice techniques is the bundle concept: the combination of a number of proven therapies to achieve a better outcome. There are a number of clinical issues for which the bundle concept has been applied. The concept includes the combination of a number of practices for which there is substantial evidence regarding their effect on improving outcome. At the same time, not all interventions that have a scientific basis to them are included in the bundle since consideration is given to ease of implementation and cost, in deciding on the components of a bundle. Therefore maximal effort to reduce complications should include the bundle as a minimum, but by no means as the sole, component of the intervention.

The Institute of Healthcare Improvement (IHI) has promoted the ventilator-associated pneumonia (VAP) bundle and the central catheter-related infection bundle among others.

Ventilator-Associated Pneumonia

Pneumonia in ventilated patients is a major clinical problem. Critically ill patients requiring ventilatory support may develop pneumonia owing to the treatment, and this nosocomial infection leads to increases in length of stay in the ICU, to increased time of mechanical ventilation and to increased mortality. It is therefore very important to decrease the incidence of VAP to improve outcome. The VAP bundle

includes a number of strategies that have been shown to reduce VAP, and are “bundled” together. There are four components of the ventilator bundle and they are elevation of the head of the bed, daily assessment of patient ability to be extubated by stopping sedation, prophylaxis for upper GI bleeding, and DVT prophylaxis.

This means that when assessing compliance with the approach to reduce VAP, complete application of the bundle is considered as compliance with the bundle. There is no partial application and measurement of complete compliance can be shown to reduce the rate of VAP. It has been shown that compliance with the VAP bundle can be achieved when staff are informed about the importance and scientific validity of the bundle, and are given feedback regarding measured compliance with the bundle. Applying these principles, Cocanour and colleagues have shown a large reduction in the VAP in a trauma ICU [13]. Others have also shown significant reductions in the incidence of VAP in critically ill patients by applying this approach [14].

Central Venous Catheter Infection

Central lines, which are an essential component in patients treated in the ICU, can lead to blood stream infections that can have a significant impact on morbidity and mortality. Almost 50% of patients in the ICU have central lines, which are used for monitoring and delivery of critical drugs. Infections associated with these central lines lead to significant burden in terms of cost, an average cost of a central line associated infection being between \$3700 and \$29 000. There is also a significant attributable increase in length of stay and mortality. The central venous catheter bundle includes the following components: hand hygiene, maximal barrier precautions upon insertion of the central line, chlorhexidine skin antisepsis, optimal catheter site selection, with subclavian vein as the preferred site for nontunneled catheters, and daily review of line necessity with prompt removal of unnecessary lines.

Applying a complex of interventions designed to reduce infections, catheter-related infections could be eliminated in a single institution [15], and in a study of a large number of ICUs it was seen that the application of a group of interventions lead to a significant and sustained reduction in catheter-related infections [16].

Who Regulates? Who Measures?

The increasing concerns over both quality and cost have led many regulatory agencies to try to enforce various process changes into critical care. Not only governmental agencies but privately organized bodies with a large consumer power such as the Leap Frog group have also determined process components that they regard as mandatory to improve outcome. Among these are the implementation of computerized physician order entry, and the staffing of dedicated intensive care physicians 24 h a day all week. The involvement of regulatory agencies is perceived by some clinicians as adding complexity to reporting and regulations without a quality or outcome benefit. However, it is a factor that will probably only increase in magnitude and lead to a growing demand on clinicians and administrators to apply best practice techniques, document, and measure them. The effect of these regulations on quality is as yet unknown.

Summary

Quality improvement in the ICU is an ongoing endeavor that begins with design of the physical aspects of the ICU and workflow structure, entails measurement of different parameters, and impacts outcome of patients, both in terms of requirement of ICU care, length of stay, and mortality.

ERAN SEGAL

Population Characteristics of Proficiency Test Data

Introduction

Silicate in seawater, acenaphthylene in sediment, and DDT in fish muscle, are some of the many chemicals found in the sea. Interpretation of information on the concentrations of such chemical contaminants in the environment is highly dependent on the reliability of the analytical measurement. The quality of these measurements is frequently assessed through a laboratory's participation in an appropriate proficiency test (PT) scheme [1, 2]. Homogeneous environmental test materials are provided for analysis and the resultant data from the chemical measurements are compared by the scheme organizer to determine the level of agreement between participants.

A statistical evaluation of the PT should provide a robust and reliable estimate of the true value and the variance of the data, without being influenced by extreme values, many of which are random in origin. The assessment of the individual laboratory performance can then be based on these estimates.

The true value of the concentration of a determinant in a natural PT is usually unknown. Therefore we need to estimate a consensus value from the data provided by the laboratories. When data are generated under statistical control they will generally be normally distributed. We can then use the arithmetic mean and standard deviation (SD) as summary statistics. In reality, however, we find that overlying any **normal distribution** are positively or negatively skewed values that can create bi- or multimodal distributions due to outliers, biased measurements, and left-censored values (LCVs). **Outlier** tests have been used with some caution to eliminate extreme values, but we need alternative methods to evaluate the nonnormal distributions generated in PTs. Robust methods using the Huber [3–5] or Hampel [6, 7] estimators effectively weigh down the effect of skewed and outlying values on the mean where they comprise <10% of the data. These methods, however, cannot cope with highly skewed data, bimodality, or LCVs.

The Cofino model [8, 9] overcomes many of these limitations by taking an alternative approach. Our model identifies clusters of values within a dataset that exhibit a high level of agreement and, for each

cluster, calculates the mean, variance, and the percentage of the whole dataset. This model, therefore, minimizes the contribution of the skewed or outlying data to the mean of the main mode of the data.

Theoretical Background

The Cofino model [8, 9] uses a **probability density function (pdf)** for each observation as a starting point. We obtain a pdf representing all data in a PT by summing each pdf associated with the individual measurement. The overall pdf is the starting point for our model. Instead of calculating the mean of the data, our model establishes the most probable value, given the overall pdf. As an analog to the wave functions in quantum mechanics, observation measurement functions (OMFs, φ_i) are defined as the square root of the pdf attributed to the individual observation, which is the key to calculating the population characteristics. The set of OMFs forms a space, or a basis set, in which we construct the so-called *population measurement functions (PMFs)*. The PMF ψ_i is constructed as a linear combination of OMFs: $\Psi_i = \sum c_{ij}\varphi_j$.

We obtain the coefficients by locating the, unnormalized, PMF₁, with the highest probability in the basis set. This probability is given by the integral $\int \psi_1^2 dc$. We use Lagrange multipliers and impose the additional constraint, that the sum of the squared coefficients is equal to one. The mathematical elaboration requires a solution to the eigenvector–eigenvalue equation $Sc = \lambda c$. In this equation, S represents the matrix of overlap integrals, with S_{ij} given by $\int \phi_i \phi_j dc$. The overlap integral S_{ij} can range between 0 (no overlap) and 1 (100% overlap) when the observations have identical pdfs.

From a set of n basis vectors, OMFs, the model creates a total of n eigenvectors, c , with eigenvalues, λ . The eigenvalue λ_i gives the probability, in the basis set, of the corresponding eigenfunction i . The highest probability and thus maximum value for λ is equal to the number of data n , which is obtained when all data have exactly the same pdf, and each OMF has a coefficient equal to $1/\sqrt{n}$. The eigenvector with the highest eigenvalue λ is the PMF₁. The remaining $n-1$ linear combinations are ranked according to probability (i.e., eigenvalue) and are denoted as PMF₂ . . . PMF _{n} . PMF₂ and higher PMFs may sometimes be additional modes, but are frequently only

2 Population Characteristics of Proficiency Test Data

clusters of data ordered according to their degree of overlap. When the squared OMFs of all PMFs are summed together over the entire concentration range, the pdf of the entire dataset is reconstructed.

For each PMF ψ_i the expectation value and variance can be calculated as follows:

$$\bar{x}_i = \frac{\int c \times \psi_i^2 dc}{\int \psi_i^2 dc} \quad (1)$$

$$s_i^2 = \frac{\int c^2 \times \psi_i^2 dc}{\int \psi_i^2 dc} - \bar{x}_i^2 \quad (2)$$

Also, the eigenvalues λ enable a quantitative assessment of the degree of comparability and the character (unimodal, bimodal) of the dataset. So we can convert the eigenvalue of the mode, or cluster proper into a percentage of the overall pdf. This percentage, therefore, quantitatively describes the fraction of the dataset that is accounted for by the PMF in question.

We have extended the model to include LCVs by defining the appropriate pdfs for these observations. The simplest approach is to assume that any concentration between zero and the limit of quantization (LOQ) has an equal probability. We can then use the square root of a rectangular pdf as basis function. Explicitly, when an LCV is reported, the basis function is equal to $\sqrt{1/LOQ}$ in the interval between zero and LOQ, or otherwise zero. These basis functions have an expectation value $\int \phi_i^2 x dx = LOQ/2$ and a variance $\int \phi_i^2 x^2 dx - \bar{x}^2 = LOQ^2/12$. Other pdf profiles, such as triangular, could be used, but we have concluded that in our studies we have no justification to use pdfs that would require more assumptions.

Inputs for the Model

In our studies we use normal distributions to define the basis functions. Therefore, in addition to the measured values, an estimate of the *within-laboratory* SD is required to define the pdfs and thus the OMFs. The *within-laboratory* SD may be calculated, for instance, when laboratories submit replicate data. The main constraint here is the ability to assess the robustness of the methods used by the laboratories to replicate the measurements.

We have specifically developed the Cofino model using a normal distribution approximation (NDA)

to apply to situations where the reliability of the *within-laboratory* SD cannot be assessed, or when *within-laboratory* SDs are not available at all [8, 9]. The NDA approach is based on the premise that the population characteristics of a normal distribution can be reproduced when each data point is given a normal distribution with the reported concentration as mean and a *within-laboratory* SD constructed as

$$SD_{NDA} = 1.168 \times \text{median}(\text{abs}(x_i - \text{median}(x))) \quad (3)$$

The NDA assumption has been fully tested and verified [8]. We have developed the model for normally distributed populations, but it will also handle nonnormally distributed populations as equally well as the robust techniques developed by Huber and Hampel [8].

Output of the Model

In this application, we have used the Cofino NDA model. We obtain both numerical **descriptive statistics** and a graphical output to aid interpretation of PT data. We have also compared similar information using the Huber and Hampel estimators. The Cofino mean, SD of each mode in the data, and the percentage of data associated with each mode were calculated. The main mode (PMF₁) accounts for >75% of data when the distribution is close to normal. In such cases, the mean and SD we obtained by the different methods of calculation are very comparable. The measurement of silicate in seawater is given as an example (Table 1 and Figure 1).

The three main graphical outputs from the Cofino statistical calculations provide an insight into the structure of the distribution (Figure 1). The pdf conforming for all data (light area) and for data in the main mode (PMF₁) (dark area), allows us to compare the measurements associated with the consensus value with that of the whole distribution. The overlap matrix of each value with all other values is obtained during the calculation which provides us with a map of the homogeneity of the data. The white area (1) denotes overlap (agreement) and the black area (0) denotes no overlap (no agreement). Modes (square areas of similar color) that can be seen within the overlap matrix are not always immediately obvious in the PMF plots (see **Multiple Modes in Proficiency Test Data**). The ranked overview provides us with the individual data (or mean of replicates) with

Table 1 A comparison of the summary statistics from the proficiency test for silicate in seawater and acenaphthylene in sediment

Matrix	Determinant	Total NObs	LCV NObs	Percentage of data in first mode	Units	Cofino		Huber		Cofino SD		Huber SD		Hampel		Hampel SD		Arithmetic		Arithmetic SD	
						mean		mean		mean		mean		mean		mean		mean		mean	
Seawater Sediment	Silicate	47	0	79	$\mu\text{mol l}^{-1}$	9.79	0.70	9.91	0.73	9.88	0.72	9.95	1.72	20.94	17.35	24.76	24.29	9.95	1.72	24.76	24.29

Histogram of data. (b) The overlap matrix. Scale 0 (no overlap of data) to 1 (complete overlap). The extensive, central light area shows a high level of agreement and homogeneity of the data. (c) Ranked overview of data $\pm 2SD_{NDA}$

the SD reconstructed from the NDA (equation 3) and also gives the location of the consensus value in relation to the distribution. The range of the LCVs is also included.

We have provided two examples for comparison. The mean and SD for silicate in seawater determined by the Huber and Hampel robust estimators differ from our model by <2%. So where data closely reflect a normal distribution, different methods of calculation can produce similar results. Larger differences between these methods of calculation arise with skewed and tailing data. The example of data from the analysis of acenaphthylene in sediment (Table 1 and Figure 2) shows almost 100% difference in the mean using the Huber estimator (23 mg kg⁻¹) and the Cofino model (12.2 mg kg⁻¹). The positive tailing values are *ca* 50% of all numerical values (Figure 2) and have a clear influence on the robust estimators compared with the Cofino model. Why is this so? In Figure 2(b) we can see that there is no overlap of the tailing data with the values associated with the first, main mode, PMF₁ and so effectively do not contribute to the construction of the mean of this mode. The Cofino model, therefore, provides a more meaningful consensus value for the purposes of this PT.

The evaluation of the LCVs by the Cofino model allows us to include all data and provide a more complete assessment. In some cases, where the concentration of the determinant is very low, the LCVs may constitute most of the data. Ignoring these LCVs can lead to a biased interpretation. We have, as an example, measurements of *op'*-DDT in fish muscle (Figure 3) where there are 6 numerical values and 11 LCVs. The LCVs and the two lowest numerical values are in good agreement while the remaining four numerical values are at considerably higher concentration, possibly due to contamination during chemical analysis. The Cofino model *without* LCVs gives a consensus value of 13.9 µg kg⁻¹ while the robust mean (Huber estimator) is 18.9 µg kg⁻¹. Using the full Cofino model *with* the LCVs, the consensus value reduces to *ca* 1.5 µg kg⁻¹, which is more in line with the range of the majority of the data. We should emphasize that in this case the consensus value would most likely be indicative, due to the high uncertainty of the consensus value.

Benefits of the Model

The Cofino model has been developed and tested for use in the determination of population characteristics specifically, but not exclusively, for PTs. The current algorithm used in the NDA implementation of the model assumes an underlying normal distribution, but has a same level of robustness as the Huber and Hampel approaches. The model can be applied to a wider range of data types.

Currently, this model provides comprehensive summary statistics for each mode in a dataset combined with an extensive graphical description of the structure of the data. These outputs are obtained in a single computation without any manipulation of the data, trimming or subjective elimination, including LCVs and missing values.

The model can be applied directly to tailing and skewed data, including extreme values (outliers) and bimodal (multimodal) distributions. In the case of bimodal data, the model may identify each mode and provide an estimate of the mean, SD, and percentage of data associated with each mode (*see Multiple Modes in Proficiency Test Data*). The model can include LCVs and has been tested on datasets with up to 60% LCVs. The model works well without the need to have the *within-laboratory* SD by using the NDA developed for this purpose. However, where these values are both available and reliable then they may provide a more sensitive replacement for the NDA.

The detailed, graphical information from the model provide a plot of the PMFs and/or of the population density functions. The color density plot of the matrix overlap is very sensitive to identifying structure of data, especially modality, where it is not so clear in other plots. Bimodality can be detected with the overlap matrix plot, even when both modes have equal density (*see Multiple Modes in Proficiency Test Data*). A ranked overview shows the means, the SD of each laboratory, and the consensus value that includes both numeric and LCVs.

The model has been fully tested with randomly generated normal distributions with the number of observations (NObs) 10–200, relative SD 2–30%, to compare performance with conventional statistics. We have also tested normal distributions overlaid to construct bimodal data. The sensitivity to bimodality, with respect to the distance, and the relative amplitude of the modes has also been tested. An evaluation

Multiple Modes in Proficiency Test Data

Introduction

Chromium in sediment and biota, chlorobiphenyls in mussels, and aluminum in sediment, are some of the many chemical contaminants in the marine environment. Proficiency Test (PT) schemes are used to provide the external quality assurance for chemical analytical laboratories that measure these types of contaminants [1]. Homogeneous natural test materials are distributed for chemical analysis on a regular basis and the returning data are assessed to determine the extent of the agreement between laboratories. Many scheme providers, such as QUASIMEME^a [2], allow laboratories to use their own optimized analytical methodology to obtain a single value for the measurement. A consensus value is obtained from these data that forms the basis of the assessment. Ideally, these data should be normally distributed, but frequently they are skewed, bi-, or multimodal. As a consequence the consensus value can be highly influenced by the distribution of these data. Many factors contribute to tailing or bimodality and it is important that we identify the data associated with each mode and, where possible, the root causes of these differences. In some instances, it is due to the relative **bias** of some procedure in the chemical analytical process. In such cases, we need to establish whether the bimodality is true or is an artefact.

We also require qualitative and, where possible, quantitative information on the degree of separation needed between modes before detection is possible and a simple screening test to identify bimodality. In addition, we require information on the population characteristics of each mode, preferably without separating the data and a clear, sensitive, graphical representation of the bimodality. We have described the Cofino model and its applications in **Population Characteristics of Proficiency Test Data** and we describe the specific problem of the evaluation of bimodal data here.

By using the Cofino model (*see Population Characteristics of Proficiency Test Data*) [3, 4] to evaluate the data, we can obtain the population characteristics (mean, standard deviation (SD) and the percentage of data attributed to that mean (λ))

for each of the population measurement functions (PMFs). In most cases, over 90% of the data are accounted for by the first two modes, PMF₁ and PMF₂ when the **normal distribution** approximation (NDA) is applied. So, for the bimodality to be significant, the data associated with PMF₂ needs to be distinct from the data associated with PMF₁. Since the data associated with both PMF₁ and PMF₂ have a known mean and SD from the Cofino model, we can use the Student's *t* test as a simple, preliminary, indicator of bimodality.

The identification of bimodality primarily depends on two factors. The first is the degree of separation between the two modes and the second, the percentage of data in each mode.

Resolution of the Modes

To test the resolving **power** of the model, we randomly generated a series of datasets to give $N(100, 2)$ with 50 values and $N(100 + i, 2)$ with 30 values, where $i = 1 : 10$. The SDs of the two populations s_{pop} are thus equal. Data for each degree of separation $N(100, 2) + N(100 + i, 2)$ were combined to provide bimodal distributions with a separation i between the modes. We then applied the Cofino NDA model to obtain the population characteristics of both modes.

In Figure 1 we have plotted the separation of the two modes expressed as i/s_{pop} (thus normalized with respect to s_{pop}) against (a) their means, (b) the ratio of the percentage of data associated with PMF₁ and PMF₂, and (c) Student's *t* value.

We detected very little separation up to a $3 \times s_{\text{pop}}$ difference in the mode means, as both distributions overlapped and influenced the mean of the two modes, PMF₁ and PMF₂. As we increased the separation, the Cofino model mean of the first mode (PMF₁) decreased to approximately the known value (100), while that of the second mode (PMF₂) increased to its known value. Simultaneously, the ratio of percentage of data in the two modes fell to that of the two independent datasets $50/30 = 1.7$.

Percentage of Data in Each Mode

The second factor affecting the identification of bimodality is the number of observations (NObs) associated with each mode.

2 Multiple Modes in Proficiency Test Data

Figure 1 The effect of separation of two overlapping distributions $N(100, 2)$ and $N(100 + i, 2)$ where $i = 1 : 10$ on the mean of data associated with PMF_1 (first mode) and PMF_2 (second mode) obtained using the Cofino model. Both modes are clearly resolved when the difference between the means $> 6\%$

In the example we assigned a ratio of 50:30 for the data in the two modes. However, if we change this ratio to 50:50 it becomes more difficult to identify and isolate the two modes due to the way in which the SD, using the NDA model, is constructed.

Again we generated and combined data with $N(100, 2)$ and with NObs from 30 to 50 in increments of 5 and a second distribution with $N(107, 2)$ and $NObs = 30$. The values for the mean of data associated with PMF_1 , and PMF_2 are plotted against the ratio of NObs in the two modes. Superimposed on this plot is the value of the Student's t value for each of the sets of data (Figure 2).

When the ratio of NObs for the two modes is 1 there is no separation. Here the values for the Cofino mean for PMF_1 and PMF_2 are 103.4 and 103.6, respectively. As we increase the ratio of NObs between the two datasets, we begin to detect separation. When the ratio of NObs exceeds 1.7 the Cofino means of the two modes are close to their independent values, the Student's t value is > 2 , i.e. t_{crit} , and there is a clear separation. Both means of the data associated with PMF_1 and PMF_2 are now close to their independent values 100.2(100) and 106.6(107) respectively.

The breakpoint for separation and obtaining the population characteristics of both modes depends both on the ratio of NObs in the two modes and on

Figure 2 The effect of the ratio of NObs in the two modes $N(100, 2)$ and $N(107, 2)$ on the mean of data associated with PMF_1 and PMF_2 . Both modes are resolved when the ratio of NObs in the two modes $> 1:1.66$

the difference between their means and their SDs. In our example, using one and the same s_{pop} of about 2% of population mean, the ratio of NObs had to be greater than 1.7 and the difference between the means greater than $3 \times s_{pop}$. Below these breakpoints it is still possible to detect the bimodality using the matrix overlap, even though the population characteristics of each mode cannot be obtained from the whole dataset (see **Population Characteristics of Proficiency Test Data**) (Figure 3b). In such a circumstance, the data

Figure 3 The PMF (upper) for all data (light shade area) and for PMF_1 (dark shades area) and the overlap matrix (lower) for the combined distributions $N(100, 2)$ and $N(107, 2)$ (a) with NObs 50:30 and (b) with NObs 50:50 in each mode. A distinct separation occurs when the means differ by $>6\%$ and the ratio of NObs is $>1:1.66$. Even when there is no evidence of separation of the modes, as in PMF profile (b – upper), the two constituent modes are distinctly evident in the overlap matrix (b – lower)

in the two modes can be identified and each subset of data treated separately. For many other datasets the assessment can be made in a single calculation. Also by inspection of the distribution of the data in the matrix-overlap plots, it is possible to identify any inhomogeneity that might otherwise go undetected.

Evaluation of the Causes of Bimodal Data in PTs

In any PT where the contents of the matrix are not characterized, we need to estimate the population characteristics of each main mode in the data and provide a clear explanation of any bimodal distribution. The Cofino model often allows us to achieve this without separating the data, while the normal arithmetic or robust mean using the Hu [5–7] or Ha [8, 9] estimators will only provide a mean value that may lie somewhere between the two modes.

Chromium in Sediment and Biota

Different laboratories extract the chromium from the sediment using either a nondestructive method or hydrofluoric acid (HF) digest (*total*), or by *partial*

digestion methods with aqua regia. For one PT, the robust mean of all data, using the Hu estimator, was 85 mg kg^{-1} while the Cofino model identifies two modes at 89 and 67 mg kg^{-1} which could be associated with *total* and *partial* digestion methods, respectively. When we subsequently separated the data into two sets according to the digestion method and reapplied the robust statistics, we obtained means of 91.5 and 69.1 mg kg^{-1} .

The level of chromium in biological tissue is generally low and contamination can easily occur during chemical analysis unless an ultraclean environment is used. Data from a PT for chromium in cod liver were bimodal, with a Cofino mean for the data associated with the main mode (PMF_1) around $110 \mu\text{g kg}^{-1}$ (Figure 4). The digestion media included hydrochloric acid, aqua regia, nitric acid, nitric acid with hydrogen peroxide, and five others unspecified. There was no clear preference for either group but most of the laboratories used nitric, with or without hydrogen peroxide. Although there was a range of different digestive media, six laboratories used an open heating (OH) system for digestion and five of these were within the upper 50% of the data, with three being in the second mode. Microwave (M) digestion and the pressure bomb (PB) formed most of the data in the first mode (Figure 4).

Although there may be other differences between methods, e.g., detection systems, there is a clear bias caused by contamination of the samples digested in open vessels.

A comparison of the data obtained by the Cofino model, the Hu and Ha estimators are given in Table 1. The mean values are also indicated in Figure 4. From the summary statistics in Table 1 and from the matrix-overlap plot in Figure 4 we see that the Cofino model provides a consensus value more closely aligned with the main mode of the data while the robust statistics give a mean between the two modes.

Chlorobiphenyl (CB105) in Mussels

CB105 is amongst the more difficult congeners to completely separate chromatographically from other CBs, in particular, from CB132. Therefore, PT data can be a result of measuring just CB105 or a mixture of CB105 and other, unseparated congeners. Higher values can also be caused by contamination due to insufficient sample cleanup. The matrix-overlap

Figure 4 The PMF (a) and the overlap matrix (b) for chromium in cod liver PT. The distribution of returning data is bimodal. The methods of sample preparation used to obtain the data in the main, mode (a) comprise microwave (M) and pressure bomb (PB), both sealed systems, and a few open vessel heating (OH). In the smaller mode at higher concentration, the positively tailing data included five out of eight laboratories that used the OH system, which suggests that this maybe a source of local contamination. C: Cofino mean, Ha: Hampel estimator, Hu: Huber estimator. Our evaluation concluded that the Cofino model provided the best estimates of means for *both* modes

plot (Figure 5a) shows two modes indicated by the lighter colored areas and two very high values (top right) The mode at the lower concentration is more homogeneous with a greater overlap of data. The second mode, at the higher concentration is more diffuse. These higher values in the second mode are most likely to be associated with an insufficiently cleaned up sample, degrading or inappropriate chromatographic column selection, and/or optimization.

The mean of data associated with the first mode at a lower concentration is $0.27 \mu\text{g kg}^{-1}$ while the second mode is about 2.5 times higher at $0.64 \mu\text{g kg}^{-1}$.

Table 1 A comparison of the summary statistics from the proficiency test for chromium and chlorobiphenyl, CB105, in mussel and aluminum in sediment. Each of these PT data shows a bimodal distribution due to different methods of analysis (see Figures 4–6). Both robust methods using the Huber (Hu) and Hampel (Ha) to estimate the mean for chromium are affected by the second mode at higher concentrations for chromium and CB105 and by the second mode at lower concentrations for aluminum. In each case, the Cofino mean estimates the mean where there is the greatest overlap of data. The Cofino model can provide the mean and SD for both modes from all data in one computation

	Determinand	Total NObs	LCV NObs	Percentage of data in first mode		Units	Cofino		Huber		Hampel		Arithmetic	
				NObs	LCV		mean	SD	mean	SD	mean	SD	mean	SD
Biota	Chromium	25	3	70	$\mu\text{g kg}^{-1}$	125.21	80.22	187.39	130.34	150.61	83.50	683.82	2139.42	
	CB105	22	0	75	$\mu\text{g kg}^{-1}$	0.31	0.16	0.42	0.24	0.39	0.18	1.08	3.12	
	Mussel	27	0	75	%	4.62	1.46	4.09	2.04	4.18	1.41	4.10	1.84	
Sediment	Aluminum													

In most cases where there is clear information on likely additive interferences, the best estimate for the consensus value is often the mode with the lower value. However, this does not always need to be the case and careful judgment with supporting chemistry is essential. Again, mean using the Hu estimator is *ca* 30% higher than that when using the Cofino model (Table 1).

Aluminum in Sediment

The selection of digestion methods affects the recovery of aluminum from minerals such as feldspar in the

sediments. A range of strong acids are normally used, with HF being amongst the most effective at breaking the crystal lattice and releasing the aluminum. Other digestive techniques used are aqua regia, nitric acid as well as nondestructive techniques such as X-ray fluorescence. Most laboratories currently use HF as the preferred digestive “wet” technique.

The results for aluminum in the marine sediment show three obvious modes in the data that are clearly visible in the overlap matrix plot (Figure 6a). The highest mode, around 7.5% Al, is probably a result of two laboratories obtaining a particularly high

Figure 5 The overlap matrix (a) and the ranked distribution (b) for chlorobiphenyl, CB105 in mussels. The highly tailing data creates a bimodal distribution caused by poor chromatographic resolution, insufficient sample cleanup or contamination (NS) during the chemical analysis which leads to elevated results for these laboratories. The data in the main mode of the distribution (S) have been generated under more optimum conditions. C: Cofino mean, Ha: Hampel estimator, Hu: Huber estimator. The Cofino model provides the best estimates of means for *both* modes

Figure 6 The overlap matrix (a) and the ranked distribution (b) for aluminum in sediment. The bimodal distribution results from different methods of sediment digest. The partial digest using acids other than hydrofluoric acid (HF) form most of the lower mode while the main mode at higher concentrations consists of total digest methods (HF) and nondestructive techniques such as X-ray fluorescence. C: Cofino mean, Ha: Hampel estimator, Hu: Huber estimator. The Cofino model provides the best estimates of means for *both* modes

value. The main mode has a concentration of 4.95% and consists almost exclusively of digestion methods involving HF or nondestructive, *total* techniques. The lower mode at 1.6% Al includes methods using aqua regia (two), nitric acid (two), nitric acid and peroxide (*partial*), as well as three laboratories using HF. The non-HF, wet techniques clearly do not extract all of the aluminum, but the use of HF *per se* does not always guarantee complete recovery of the element. The robust estimates are again affected by the second mode at lower concentration, due mainly to the data obtained by the partial digest of the sediment. In this case, the most homogeneous and reliable consensus value was based on the main mode at the higher concentration.

Benefits of the Cofino Model

Using the Cofino model we are able to estimate the population characteristics of each mode in a bi- or multimodal distribution. In most cases, we can achieve this using the whole dataset, including left censored values (LCVs), without the need to trim the data or remove outliers. The resolution between the modes depends on the ratio of data in the two modes and on the difference between the means in relation to the SDs of the modes. However, even in unfavourable conditions, the matrix overlap plot will still suggest the presence of two modes.

Evaluation using the Hu or Ha robust estimator will provide similar consensus values where the tailing and **outlier** values are *ca* < 10% of all data, but unlike the Cofino model, these techniques are less able to cope effectively with heavily tailing or bimodal data. In some cases, as we have shown here, the robust mean using these estimators can occur between the modes where there are very few data. The combination of the information gained from the Cofino model with scientific expertise will, in many cases as shown above, enhance the reliability of interpretation of PT data.

End Note

^a. QUASIMEME, Quality Assurance of Information for Marine Environmental Monitoring (in Europe),

funded initially by the EU (1992–1996) for European Laboratories, is now a worldwide project funded by the subscribing participating laboratories www.quasimeme.org.

Acknowledgments

The authors wish to acknowledge the members of the QUASIMEME team, in particular Judith Scurfield, in testing this model, and the participants of the QUASIMEME scheme for providing invaluable data for evaluation. The authors would also like to acknowledge Ian Davies for his helpful critical review of the manuscript.

Disease and Clinical Trial Modeling

Introduction

Clinical trials are considered the gold standard among the experiments aimed at providing scientific evidence on the effects of treatments and other factors that determine the progression of diseases. However, clinical trials are often long and expensive, and their results are uncertain. Moreover, they pose individuals at risk. It is therefore important to ensure that their objectives will be met at the lowest possible cost in terms of health and resources. Poorly designed clinical trials might fail in assessing the hypothesis tested with the required level of statistical significance, which means that resources will have been wasted and patients will have been unnecessarily put at risk. Modeling techniques allow decision makers to explore the consequences of their decisions in planning processes and activities and to identify the best courses of action under uncertainty [1, 2].

Modeling has been used for a long time in the field of clinical research as an aid for ensuring the attainment of positive results of experiments at the stage of experimental design. But disease and clinical trial modeling may have broader goals and take place at different phases of the trial. A model might sometimes be specified in a way that allows solving it by analytical methods, often providing a single solution, but this is often not the case. Simulation might then provide a better methodological approach, especially in dealing with complexity and uncertainty, as it is usually the case in health research. The models most widely used for assessing the effects of pharmaceuticals and other healthcare technologies are discrete health states and stochastic models, where health is represented by variables that change at discrete periods of time [3]. Although simulation has sometimes been used to extrapolate trial results when cost or time restrictions did not permit performance of a new clinical trial, simulation has mainly been used to explore in advance the likely outcomes of future or hypothetical trials; for instance, simulation was employed to illustrate the possible reasons why a randomized trial of an acute stroke treatment might be underpowered [4]. When applied to the design and management of clinical trials, modeling can increase

the likelihood of success and reduce the costs of failures and the inefficient performance of clinical trials.

From an economic perspective, the global objective of a clinical trial can be formulated in terms of a function whose arguments are statistical **power**, total duration, and cost of the clinical trial, because these three variables determine the net profit of putting a pharmaceutical product or health technology in the market from the point of view of a private investor. We assume that the investor tries to maximize the net profit of a clinical trial by maximizing the present value of the stream of costs and revenues related to the product. We further assume that for a limited period the product will benefit from market exclusivity that allows it to be sold at a price that yields extraordinary profits. A shorter duration of the trial would lead to a longer period of high monopoly price of the drug. A higher statistical power, in its turn, will lead to a higher probability of obtaining market approval, which is a condition for obtaining revenues and, hence, profits from the sales of the product under evaluation.

If we define *ENB* as the total expected net benefits, *NBM* as the net average extraordinary profit from annual sales, *n* as the duration of the product life cycle, *P_e* as the success probability of marketing the product under trial, *C_t* as the total cost of clinical trial, and *d* as the total duration of the clinical trial, *ENB* can be expressed as

$$ENB = P_e \cdot NBM \cdot (n - d) - C_t \quad (1)$$

The objective of this paper is to show how simulation modeling can be used to estimate the *P_e*, *d*, and *C_t* that result from a certain trial design or from similar decisions. Together with some estimates of *NBM* and *n* from other sources, decision makers might be able to assess and maximize the expected net profits of a clinical trial as represented by the expression (1). In the third section of the article, the previous analysis is illustrated with the results of a case study with both actual and hypothetical data.

Methods

The general model for optimization of a clinical trial that we propose in this work consists of three basic elements: structure, parameters, and assumptions. The structure is based on two submodels. The first one

2 Disease and Clinical Trial Modeling

is the recruitment submodel, which represents the arrival of volunteers at the center and their posterior inclusion in the trial. Its objectives are to estimate the time and cost required for completing the process of recruitment of patients in the trial. This process will depend on several factors, such as, the number of patients required, the number and capacity of the centers involved in the trial, the arrivals rates of volunteers to the centers at each time period, and the probability of inclusion of the patients in the trial.

The second one is the follow-up submodel, which describes the course of the disease under the various options evaluated. The disease progression is represented by a statistical model considering either continuous and/or discrete health states to evaluate changes in response variables. For example, the evolution of the cholesterol level over time can be modeled as a continuous variable that changes at discrete periods of time or as discrete health states, which are then defined in terms of the cholesterol level. In the second case, the progression of patients between health states depends on certain predefined transition probabilities. These probabilities depend on time and patient characteristics, such as age, morbidity, and on initial and intermediate health states.

Parameters are classified in two categories, the first one includes statistical significance test, endpoints, number of centers, and duration of follow-up, which are considered as trial design variables, and whose characteristics and values vary within certain constraints. Some of these constraints might be imposed by the clinical trial regulation agency or by traditional practice. The second category represents the external variables that may affect the final results of the trial. These are recruitment rate, center capacity, inclusion probability, inclusion cost, cost per center, treatment effects, probability of withdrawal, and non-compliance. Other external variables such as resource use and unit costs of resources are integrated into the model in order to assess the economic outcomes, e.g., the total cost of the trial. Variables might be integrated into the model as fixed parameters, as endogenous variables with either parametric or empiric distribution, or as restrictions.

Figure 1 illustrates construction of a disease and clinical trial model, based on assessing the likely effects of alternative trial designs, which in economic terms means choosing combination of inputs and transforming them into outputs. The analyst can predict which design maximizes the target function.

Figure 1 Disease and clinical trial model construction

Data is used to construct the model and adjustments to the structure of the model, later, can be incorporated based on different expert opinions: clinicians, statisticians, economists, and informatics. The objective is to adapt the model to parameters that come from different sources. Simulation is performed in order to calculate the P_e , d , and C_t . Design parameters were integrated assuming a range of values for each of them and simulation is carried out again in order to calculate the expected net benefit.

The optimization of a clinical trial design can be performed by selecting different feasible combinations of the input parameters and executing the clinical trial model. This can be carried out with the help of an automatic strategy that explores the outcomes of different combinations of design variables; finally, the results are evaluated using an optimization

target function such as equation (1). By carrying out simulations with the appropriate number of repetitions of each possible combination, the designer of a clinical trial can explore the value of the optimization function within the assumed restrictions. In order to assess the robustness of the results, sensitivity analysis can easily be carried out using a range of possible parameter values and scenarios.

Results

We applied the approach explained above to a case study of real clinical trial conducted and described by Negredo *et al.* [5] from the Hospital Universitari Germans Trias i Pujol. The main objectives of this trial were to compare the efficacy of three regimes, one protease inhibitor (PI)-containing regime and two PI-sparing regimes, including nevirapine or efavirenz, to maintain the suppression of plasma HIV-1 RNA and to allow the progressive immunologic improvement of patients. Secondary objectives were to assess the impact of PI-sparing regimes on the metabolic profile, on other adverse events and on quality of life. The trial was also aimed at evaluating the variations in body-shape occurring in patients suffering lipodystrophy at baseline. The 100 patients who had been receiving a PI-containing regime and who had long-lasting plasma HIV-1 RNA were recruited after 12 months and were randomized to either continue with the same therapy or to have the PI replaced by nevirapine or efavirenz. These patients were followed for up to 1 year. Only 49 patients completed the trial (23 in the PI-sparing arm and 26 in the PI-based antiretroviral therapy) and only the data of these patients were used to illustrate the applicability of our simulation model, although it can be easily extended to account for the influence of this missing data on the simulation results in a sensitivity analysis.

The structure of the model was adjusted according to the opinions of clinical, statistic, and economic experts. Design parameters including, different methods to quantify the endpoint, number of centers, were identified. Then, unit cost parameters were incorporated in order to estimate the total cost of the trial as function of statistical power, and the duration considering different sample sizes, number of centers, and center capacities. The unit costs were €6500 per center, €60 per patient recruited, and €60 for

patient follow-up, and the monthly cost of delaying the finalization of the trial could be estimated as €6000. The design that minimizes both duration and cost was achieved with eight centers and a duration of 10 months, leading to the evaluation of the effect of the treatment on 300 patients. Thus, the estimated duration and cost were 7.70 months and €120 200, respectively.

We finally substituted the resulting power, duration, and cost by the P_e , d , and C_t in formula (1) to assess the expected net profits. Assuming the remaining time until the expiration of the product to be 10 years, $ENB = 0.83 \times 6000 \times (10 \text{ years} \times 12 \text{ months} - 7.70 \text{ months}) - 120\,200 = €547\,234$.

Conclusions

The approach proposed in this work allows substantial improvements in clinical trial design and management. Moreover, simulation models integrate clinical research with statistics, economics, and computer disciplines, in order to optimize the global results of clinical trials in terms of economic benefits. The same approach can be used to assess the social value of a clinical trial, by reformulating equation (1) in terms of socially relevant effects, i.e. health and resource effects.

For simplification purpose, deterministic calculation was performed to determine the expected net benefits, where uncertainty has not been considered. Nevertheless, when we consider uncertainty, the simulation can be easily used to perform a large number of replications with all possible input combinations. Hence, the expected value is calculated for each combination, and the highest value is chosen to decide the **optimal design** of the trial. The model can be conveniently adjusted to specific conditions in order to represent a planned clinical trial and to prospectively simulate the results for alternative designs and assumptions.

The approach is being applied to phase III clinical trials, although it can also be applied to other phases. Finally, there is the possibility of applying it in real-time practice, such as in the follow-up period of a clinical trial, in order to inform stop-go decisions, possible increases in the numbers of patients or centers, and so on. The model might also be improved by progressively incorporating on-going information and results of the trial.

Statistical Process Control in Clinical Medicine

Introduction

The quality of a clinical process may be assessed provided it is in a state of statistical control, i.e., predictable. **Control chart** techniques originally developed for industrial **process control** [1] may be applied to develop and monitor the quality of a clinical process [2]. However, if the quality measure/indicator used is an outcome measure, e.g., mortality following a coronary artery bypass graft operation, its value depends not only on the quality of the clinical process, but also on risk factors, e.g., severity of the patient's disease, comorbidity, age, sex, etc. Various risk-adjusted control charts may then be used [3], although the results obtained should be considered provisional, requiring further investigation.

Outcome results of several healthcare providers (physicians, hospital departments, etc.) may be compared if the patients are assigned at random to the providers. Usually (but not always [4]) this is not possible for practical and/or economical reasons. Then, one has to use observational data. The influence of patient case-mix differences between the providers, therefore, has to be adjusted for prior to the comparison [5]. This is usually (but not always [6, 7]) achieved by regressing the provider category and important risk factors on the outcome. The approach is fraught with problems. In the following we will present the statistical techniques used in this paper, demonstrate the construction and subsequent use of a control chart by way of a straightforward example, and illustrate and discuss the perils of risk adjustment.

Methods

Control Chart

A control chart is used to characterize a clinical process and subsequently to monitor it. The chart depicts the values of a measurable quantity characterizing the process, e.g., the fraction of patients dying per month during a specified surgical procedure, the weekly mean of patients' waiting times until seen by

a physician, the cost per patient treated for a hip fracture, etc. If a clinical process is in statistical control, the causes of variation cannot be determined, but the results follow a probability distribution that characterizes the process. Its mean (μ) and standard deviation (σ) define the state of the process. A control chart is constructed, using 20–30 samples obtained while the process was in statistical control. It is furnished with a centerline (the grand mean of the samples), an upper and a lower control limit (the grand mean plus, respectively minus three times the *sample* standard deviation), and a time axis. The control limits are constructed so that as a rule the sample means will be located within the control limits when the process is in statistical control. If a sample mean falls outside the control limits, the added variation has an **assignable cause** with a high probability, and a search for this is initiated.

Measuring the Quality of a Process

Assume that the results of a clinical process in statistical control follow a Gaussian distribution with mean μ and standard deviation σ , which are known. Let the upper specification limit (USL) be a value separating acceptable results from unacceptable results that are larger than this value. Then, $C_{pu} = (USL - \mu)/(3\sigma)$ is a measure of the quality of the process. If C_{pu} is 1.00, 0.135% of the values of the process are expected to be $\geq USL$, and if it is > 1.00 , less than 0.135% are, provided the true μ and σ are known. According to industrial standards $C_{pu} \geq 1.66$ is an acceptable quality. If the parameters are not known the **sample size** should be 100 or more [8].

Logistic Regression

Let p_{ij} be the probability that patient i , treated by healthcare provider j , dies; $\text{logit}(p_{ij})$ is the logarithm of the corresponding odds ($p_{ij}/(1 - p_{ij})$), X_{vij} is the v th quantity that is measured in this patient and is related to the probability, and $H_j (j = 1, \dots, k - 1)$ is an indicator variable that is equal to 1 if the patient is treated by healthcare provider j and 0 otherwise (provider k of the k providers serves as a reference, and $k > 1$). A logistic regression model is defined by $\text{logit}(p_{ij}) = \alpha + \sum \delta_j H_j + \sum \beta_v X_{vij} + \varepsilon_{ij}$ where α is a constant, β_i and δ_j are regression coefficients and ε_{ij} a random error. If β_v is significantly different from 0, risk factor v is significantly related to $\text{logit}(p_{ij})$

2 Statistical Process Control in Clinical Medicine

and thereby to p_{ij} . If an overall test shows that the intercepts of the providers differ significantly, the significance of the individual δ_j 's may be assessed in the same way as the β_v 's. This fixed-effect model is adequate for the example discussed in this paper because there are only two providers and the values are statistically independent. When this is not the case, a hierarchical model is preferable [9, 10].

Simulation

Assume, e.g., that we have two types of patients. The probability that a type-1 patient dies during a specified and properly administered surgical procedure is 10%, and the probability that a type-2 patient dies is 30%. If these probabilities are constant over time, the quality of the surgical procedure is stable. The behavior of such a process over time may be simulated. Assume we wanted to simulate the outcome of 1000 consecutive type-1 patients subjected to the surgical procedure. Performing 1000 independent experiments each simulating the outcome of one consecutive patient does this. Each experiment is a random draw of one ball from an urn, containing 10% red balls and 90% white balls. Thus, the probability of drawing a red ball is 10%, simulating the 10% probability of death during operation. If we wanted to simulate the outcome when a mixture of type-1 and type-2 patients were operated, we would use two urns, one for type-1 patients containing 10% red balls and another for type-2 patients containing 30% red balls. Instead of drawing balls from urns the experiments may be done using standard statistical packages.

Example of the Construction and Use of a Control Chart

Problem

At an outpatient clinic the management was notified that the USL for a patient's waiting time from arrival until blood sampling and/or electrocardiogram (ECG) recording begins is 30 min.

Design of Experiment

The management decided to take random samples comprising 30 outpatients on each weekday for

four weeks, to study the patient waiting times. The employees at the outpatient clinic were not aware of this investigation. The waiting time from arrival until seen by a technologist was recorded for each patient.

Analysis of Data

The mean and standard deviation of each sample was calculated. The grand mean ($\hat{\mu} = 15.93$ min) estimates the process mean. An unbiased estimate of the process standard deviation ($\hat{\sigma}$) is calculated by dividing the average of the sample standard deviations by a factor removing the **bias** [1]. Dividing this estimate by $\sqrt{30}$ (here the sample size is 30) one obtains an estimate of the standard deviation of the sample mean.

Figure 1 shows the $\bar{X}$ chart with the control limits equal to the mean ± 3 sample standard deviations. The observed sample means are depicted on the chart. Three of the values (samples 5, 10, and 15 all sampled on a Friday) are located above the upper control limit (UCL). Therefore, in all likelihood the process is not in statistical control. When these values were removed and a new chart calculated using the remaining values (chart not shown), the value corresponding to the fourth Friday (sample 20) lay above the UCL.

It turned out that on Fridays the patient mix differed from the other weekdays in that an unusual large number of patients from the cardiology department were scheduled for ECG recordings in addition to blood specimen collection. These patients required more time than patients not scheduled for ECG recordings, and a retrospective analysis revealed

Figure 1 Mean waiting time of patients received at an outpatient clinic on weekdays

Table 1 Procedure for investigating outlying values of daily mean waiting times (start at step 0 and proceed from left to right)

Step	Actions	Questions and routing in table	
0	Control data and data processing	Data error?	If yes go to step 4 If no go to step 1
1	Compute production in number of venipuncture equivalents. Control staffing of ambulatory	Production or staffing changed?	If yes go to step 4 If no go to step 2
2	Define productivity as venipunctures/technologist hour. Compute (a) average productivity (b) average productivity for each 30-min period (c) average productivity for each technologist (d) average productivity for each technologist in each 30-min period. Identify significantly outlying values	Go to step 3	
3	Interview manager of ambulatory and technologists	Go to step 4	
4	Write report and stop		

that overtime was much more usual on Fridays than on any other weekday.

Figure 2 shows the control chart based on the remaining values. The points marked as crosses correspond to the Fridays. Now, the process seems to be in control. The management reorganized the technologist shifts and staffing. New data were collected for a 3-week period and a new control chart made using these data. This chart was similar to that shown in Figure 2. The management purchased a system for automatic recording of waiting times. The ID of a technologist servicing a given patient was already automatically captured by the current clinical data-processing system. They designed a protocol (see

Table 1) to be followed if values outside control limits were found. The estimated process mean and standard deviation were 15.72 and 4.85 min respectively. The C_{pu} calculated to assess the quality of the process was $(30.00 - 15.72)/(3 \times 4.85) = 0.98$, based on a sample size of $15 \times 30 = 630$. This is a questionable quality according to industrial standards. The management, therefore, (a) reorganized and upgraded the staffing, (b) collected new data, and (c) calculated C_{pu} to see if the state of the process had improved sufficiently. They repeated this cycle until the quality was acceptable. Using the resulting control chart, they subsequently monitored the quality of the process by plotting the mean values on the chart and used the procedure in Table 1 to track assignable causes of excess variation.

Figure 2 Mean waiting time of patients received at an outpatient clinic on weekdays. The crosses represent mean values recorded on Fridays. They were not used when the control chart was calculated

Perils of Risk-Adjusting Observational Data

A process variable like the above is straightforward to use for monitoring a single clinical process and for comparing several healthcare providers during a specified period. If the variable is an outcome measure in patients, risk adjustment may be necessary to adjust for variation between the patients in terms of severity of disease, comorbidities, etc. [3]. However, statistical risk adjustment of observational data has the potential of generating results that may be very misleading [11]. Thus, great care should be taken when applying the results. The following study simulates a

4 Statistical Process Control in Clinical Medicine

Table 2 The results of a simulation study where the probability of death during a surgical procedure as a function of two risk factors (presence of a genetic trait and presence of infection of the organ operated on) was simulated. The probability of death for given risk factor combination, is the same in the two hospitals, but the case mix differs between the hospitals

Hospital ^(a)	Genetic trait ^(b)	Infected organ ^(c)	Simulated model ^(d)	Result of simulation ^(e)		Genetic trait assumed unknown ^(f)	
				Mortality ^(g)	<i>n</i> (number of dead) ^(h)	Mortality ⁽ⁱ⁾	<i>n</i> (number of dead) ⁽ⁱ⁾
1	No	No	$p = 0.100$	0.060	100 (6)	0.227	300 (68)
	Yes	No	$p = 0.300$	0.310	200 (62)		
	No	Yes	$p = 0.300$	0.300	200 (60)		
	Yes	Yes	$p = 0.600$	0.574	500 (287)		
2	No	No	$p = 0.100$	0.096	700 (67)	0.131	840 (110)
	Yes	No	$p = 0.300$	0.307	140 (43)		
	No	Yes	$p = 0.300$	0.233	120 (28)		
	Yes	Yes	$p = 0.600$	0.825	40 (33)		

^(a) It is assumed that the quality of treatment and care is the same at the two hospitals.

^(b) The presence of the genetic trait influences the probability of death (see parameters of simulation model in column 4).

^(c) The presence of infection of the organ operated on influences the probability of death (see parameters of simulation model in column 4).

^(d) The parameter value of the simulation model generating the data. For instance when the genetic trait is present and the organ is infected the probability of death is 0.600.

^(e) Columns 5 and 6 show the result of the simulation for each combination of risk factors in each hospital.

^(f) Columns 7 and 8 show how the results would have been classified had the information of the genetic trait been unknown to the medical community. For instance, the results of the two first set of experiments would have been pooled and classified as data from patients without organ infection, etc.

^(g) The mortality observed in each of the eight sets of simulation experiments. When compared to the value in column 4 one may appreciate the effect of the random variation.

^(h) *n* is the number of independent simulations done per experiment. *n* has been varied between the hospitals to imitate difference between the case mix of the two hospitals. Number of dead is the number of fatal outcomes occurring during the *n* simulations.

⁽ⁱ⁾ Using the same data that were generated by the simulation. For given value of “infected organ” and given hospital the data have been pooled imitating the situation where the risk factor “genetic trait” is unknown to the medical community.

simple and intuitively obvious mechanism whereby misleading results may be produced.

Imagine two hospitals both receiving patients belonging to the same well-defined clinical entity and suffering from the same grave disease that requires major surgery. Assume that the same surgical procedure is used in both hospitals and that two patient factors influence these patients’ risk of dying during operation: the presence of a specific genetic trait (R_1 : 1 if the factor is present, otherwise 0) and the presence of infection of the organ to be operated on (R_2 : 1 if present, otherwise 0). Patients with neither risk factor present have a 10% probability of dying during the procedure, regardless of the hospital they are admitted to. For patients with one factor present the probability is 30%, and for those with both factors present it is 60%.

We now conduct a simulation experiment based on the above mentioned assumptions simulating the

experience of 2000 patients admitted to the two hospitals. To study the effect of patient case mix we vary the patient case mix between the hospitals. We examine the effect of risk adjustment when both risk factors are known and when only risk factor 2 is known.

Table 2 shows for each of the above two hospitals the case mix of 1000 patients admitted to the hospital and the results of the simulation experiments. These results have been analyzed under the assumption that both risk factors are known to the medical community (columns 5 and 6) and under the assumption that only one is known (columns 7 and 8). For example row 1 shows the simulated probability of death in column 4. It is 0.100 because the patients of this category do not have any of the two risk factors present (see columns 2 and 3). The result of the simulation of 100 patients’ experience is that 6 patients died (column 6). Row 2 shows the corresponding results for patients

with risk factor 1 present and risk factor 2 absent. Here the simulated probability of death is 0.300 and the result of the simulation that 62 of the 200 patients died giving a simulated death rate of 0.310. Columns 7 and 8 show how the results would have been interpreted had risk factor 1 been unknown to the medical community. Now the two types of patients cannot be distinguished and we calculate the mortality for patients with risk factor 1 absent as $68/300 = 0.227$, etc.

The overall mortality rates (hospital 1: 0.415 and hospital 2: 0.171) differ significantly between hospitals. However, we need to adjust for the difference in case mix. To do so, we perform a regression of risk factors and the hospital effect on $\text{logit}(p_{ij})$ where p_{ij} is the probability that patient i , treated at hospital j , dies. The independent variables include R_1 , R_2 , and H_1 (1 if the patient is treated at hospital 1 and 0 if treated at hospital 2). We have the model

$$\text{logit}(p_{ij}) = \alpha + \delta_1 H_1 + \beta_1 R_1 + \beta_2 R_2 + \varepsilon_{ij} \quad (1)$$

Table 3 shows the result of the logistic regression analysis. The coefficients of both risk factors are highly significantly different from 0 while that of the hospital effect is not. This is no surprise to us because we conducted the experiment so that the hospitals only differed in terms of their case mixes.

Table 2 (columns 7 and 8) shows how the data resulting from the simulation would have been classified had the genetic trait been unknown. Patients

with both risk factors present would not be distinguishable from patients with only risk factor 2 present and patients with only risk factor 1 present would be classified as low-risk patients. The logistic regression model therefore becomes

$$\text{logit}(p_{ij}) = \alpha + \delta_1 H_1 + \beta_2 R_2 + \varepsilon_{ij} \quad (2)$$

Table 3 shows that now the hospital coefficient is significantly different from 0 implying that the mortality rate of hospital 1 is higher than that of hospital 2 even if we adjust for case-mix differences. Thus, the presence of an unknown or unmeasured significant risk factor may bias the comparisons between healthcare providers. Needless to say that following a simulation of random assignment of the patients to the two hospitals the death rates did not differ significantly, neither with nor without risk adjustment.

Empirical studies [11] have demonstrated that statistical adjustment of observational data may fail to remove the main part of bias and occasionally dramatically increase systematic bias. This may, e.g., result from omitted or unknown risk factors (as illustrated in the above example), mis-specification of continuous variables (inappropriate conversion to binary variables or failure to recognize nonlinear relationships), misclassification through the use of poor proxies for the proper **covariate**, measurement errors, and within patient instability in covariate (e.g., because of circadian rhythms). As a minimum

Table 3 The estimated coefficients of two logistic regressions of hospital (H_1)^(a) and risk factors^(b) (R_1 and R_2) on $\text{logit}(p)$, where p is the probability of dying during an operation. In the first regression analysis^(c) both risk factors were known. In the second analysis^(d) it was assumed that only one of the risk factors (factor 2) was known, imitating the situation where an important risk factor is unknown to the medical community

Parameter	All risk factors known				One risk factor assumed unknown			
	Estimate	SE ^(e)	p ^(f)	Estimated odds ratio ^(g)	Estimate	SE	p	Estimated odds ratio
β_2	1.30	0.127	<0.00005	3.67	1.29	0.123	<0.00005	3.63
δ_1	-0.139	0.144	0.34	0.871	0.57	0.125	<0.00005	1.77
β_1	1.46	0.127	<0.00005	4.32	Factor assumed unknown			

^(a) H_1 is a binary variable that is 1 if the patient was operated at hospital 1 and 0 if he/she was operated at hospital 2.

^(b) Risk factor 1 (R_1), "presence of genetic trait". $R_1 = 1$ if trait is present, otherwise 0. Risk factor 2 (R_2), "presence of infection" in organ operated on'. $R_2 = 1$ if infection is present, otherwise 0.

^(c) $\text{logit}(p) = \alpha + \beta_1 R_1 + \beta_2 R_2 + \delta_1 H_1 = -2.23 + 1.46R_1 + 1.30R_2 - 0.139H_1$.

^(d) $\text{logit}(p) = \alpha + \beta_2 R_2 + \delta_{11} = -1.86 + 1.29R_2 + 0.57H_1$.

^(e) SE = **standard error** of estimate.

^(f) p-value.

^(g) e^{estimate} . For example for the parameter β_2 we have $e^{1.30} = 3.67$.

the following six points may be considered when statistical risk adjustment of observational data is attempted:

1. Data are first presented without adjustment.
2. Continuous variables such as age, weight, etc., are not dichotomized since this throws away information and increases the likelihood of improper model specification.
3. The assumptions of the model building such as linearity, etc. are checked (see [12]).
4. When appropriate, a hierarchical model is used [9, 10].
5. The variation not accounted for by the risk-adjustment model is measured and reported.
6. As a rule of thumb observational data are considered hypothesis generating material and treated accordingly and very explicitly presented as such.

Coherent Systems

The Structure of a Coherent System

Consider a system with n components. Let c_i denote the i th component. For now, we will consider a fixed time t . Define

$$x_i = \begin{cases} 1, & \text{if } c_i \text{ works} \\ 0, & \text{if } c_i \text{ fails} \end{cases} \quad (1)$$

The state of the system depends solely on the state of its components. A system works if certain combinations of components work. Define

$$\phi(x) = \begin{cases} 1, & \text{if system works} \\ 0, & \text{if system fails} \end{cases} \quad (2)$$

where $x = (x_1, \dots, x_n)$.

The function $\phi : \{0, 1\}^n \rightarrow \{0, 1\}$ is called the *structure function* of the system. Let us take a look at some examples. A *series system* works if and only if all of its components work. So,

$$\phi(x) = \min\{x_1, \dots, x_n\} = \prod_{i=1}^n x_i \quad (3)$$

A *parallel system* works if and only if at least one of its components works. So,

$$\phi(x) = \max\{x_1, \dots, x_n\} \quad (4)$$

Define the *cup operator* $\coprod$ through its Boolean addition properties:

$$0 \coprod 0 = 0 \quad (5)$$

$$0 \coprod 1 = 1 \quad (6)$$

$$1 \coprod 0 = 1 \quad (7)$$

$$1 \coprod 1 = 1 \quad (8)$$

We can write the structure function for a parallel system as

$$\phi(x) = \coprod_{i=1}^n x_i \quad (9)$$

Note that for all $x \in \{0, 1\}^n$, $\coprod x_i = 1 - \prod (1 - x_i)$. Clearly, $\prod x_i \leq \coprod x_i$.

A **k-out-of-n system** works if and only if at least k of its components work. The structure function for a 2-out-of-3 system may be written as

$$\phi(x) = (x_1 x_2) \coprod (x_1 x_3) \coprod (x_2 x_3) \quad (10)$$

Define

$$(1_i, x) = (x_1, \dots, x_{i-1}, 1, x_{i+1}, \dots, x_n) \quad (11)$$

$$(0_i, x) = (x_1, \dots, x_{i-1}, 0, x_{i+1}, \dots, x_n) \quad (12)$$

A structure function ϕ may be represented as

$$\phi(x) = x_i \phi(1_i, x) + (1 - x_i) \phi(0_i, x) \quad (13)$$

for any fixed i . This is known as the *pivotal decomposition of a structure function*.

Definition 1 The i th component in a system with structure function ϕ is irrelevant if

$$\phi(1_i, x) = \phi(0_i, x) \quad (14)$$

for all x . Otherwise, we say the i th component is relevant.

Definition 2 A structure function is monotone if

$$x_i \leq y_i, \text{ for all } i, \text{ implies } \phi(x) \leq \phi(y) \quad (15)$$

A component is *relevant* when there exists at least one case where the state of the system depends on whether the component works or has failed. A structure function is *monotone* when the state of the system will never improve after the failure of a component.

Definition 3 A system is coherent if each of its components is relevant and its structure function is monotone.

A coherent system consists of components that, when working, never harm the system and improve the system in at least some instance. Thus, each working component is beneficial to the system.

There are five coherent systems with $n = 3$ components. The different structure functions are

$$\phi_1 = x_1 x_2 x_3 \quad (16)$$

$$\phi_2 = x_1 \coprod x_2 \coprod x_3 \quad (17)$$

2 Coherent Systems

$$\phi_3 = (x_1 x_2) \coprod (x_1 x_3) \coprod (x_2 x_3) \quad (18)$$

$$\phi_4 = x_1 \coprod (x_2 x_3) \quad (19)$$

$$\phi_5 = x_1 \left(x_2 \coprod x_3 \right) \quad (20)$$

There exists 20 coherent systems with $n = 4$ components. The interesting question of how many coherent systems exist in general for n components is open.

It seems reasonable to say that system B with structure function ϕ_B is better than system A with structure function ϕ_A if

$$\phi_A(x) \leq \phi_B(x) \text{ for all } x \in \{0, 1\}^n \quad (21)$$

with a strict inequality at least once.

Theorem 1 For any coherent system in n components with structure function ϕ ,

$$\prod_{i=1}^n x_i \leq \phi(x) \leq \coprod_{i=1}^n x_i \quad (22)$$

Proof Let $\mathbf{0} = (0, \dots, 0)$ and $\mathbf{1} = (1, \dots, 1)$. All coherent systems have the property that $\phi(\mathbf{0}) = 0$ and $\phi(\mathbf{1}) = 1$.

If $\prod x_i = 1$, then $\coprod x_i = 1$ and $x = \mathbf{1}$. Since $\phi(\mathbf{1}) = 1$, the result is established.

If $\prod x_i = 0$, then $\prod x_i = 0$ and $x = \mathbf{0}$. Since $\phi(\mathbf{0}) = 0$, the result is established.

If $\prod x_i = 0$, and $\coprod x_i = 1$, then the result is trivial.

Thus, as one would believe intuitively, the series system is the worst arrangement of components in a coherent system and the parallel system is the best.

The Reliability of a Coherent System

Suppose components $c_1, \dots, c_n$ for a coherent system have probabilities of working at a fixed time t defined as $p_1, \dots, p_n$, respectively. The *reliability* of a system is the probability that the system works. Let $p = (p_1, \dots, p_n)$. The system reliability as a function of p is defined as

$$h(p) = P\{\phi(x) = 1\} \quad (23)$$

Assume that the component states are stochastically independent of each other. That is,

$$X_1, \dots, X_n \sim \text{indep BIN}(1, p_i) \quad (24)$$

So $E\{X_i\} = p_i$. The state of the system is also a binary random variable,

$$\phi(X) \sim \text{BIN}(1, h(p)) \quad (25)$$

so $E_p\{\phi(X)\} = h(p)$.

For a series system, the reliability function becomes

$$\begin{aligned} h(p) &= E\left\{\prod_{i=1}^n X_i\right\} \\ &= \prod_{i=1}^n E\{X_i\} = \prod_{i=1}^n p_i \end{aligned} \quad (26)$$

For a parallel system, the reliability function becomes

$$\begin{aligned} h(p) &= E\left\{\coprod_{i=1}^n X_i\right\} = E\left\{1 - \prod_{i=1}^n (1 - X_i)\right\} \\ &= 1 - \prod_{i=1}^n E\{1 - X_i\} \\ &= 1 - \prod_{i=1}^n (1 - p_i) = \prod_{i=1}^n p_i \end{aligned} \quad (27)$$

It is tempting to believe that $h(p)$ may be obtained from $\phi(x)$ simply by replacing x_i with p_i . This is not so. Consider the following example with

$$\begin{aligned} \phi(x) &= x_1 \left(x_2 \coprod x_3 \right) \\ &= x_1 (1 - (1 - x_2)(1 - x_3)) \\ &= x_1 x_2 + x_1 x_3 - x_1 x_2 x_3 \end{aligned} \quad (28)$$

So

$$\begin{aligned} h(p) &= E\{X_1 X_2 + X_1 X_3 - X_1 X_2 X_3\} \\ &= p_1 p_2 + p_1 p_3 - p_1 p_2 p_3 \\ &= p_1 \left(p_2 \coprod p_3 \right) \end{aligned} \quad (29)$$

Since x_1 is a binary variable, we have $x_1^2 = x_1$. We could alternatively write the structure function as

$$\begin{aligned} \phi(x) &= x_1 x_2 + x_1 x_3 - (x_1 x_2)(x_1 x_3) \\ &= (x_1 x_2) \coprod (x_1 x_3) \end{aligned} \quad (30)$$

But $p_1^2 \neq p_1$, so

$$p_1 (p_2 \coprod p_3) \neq (p_1 p_2) \coprod (p_1 p_3) \quad (31)$$

A pivotal decomposition can be defined for the reliability function h . Let $h(1_i, p) = E\{\phi(1_i, X)\}$ and $h(0_i, p) = E\{\phi(0_i, X)\}$. Then

$$\begin{aligned} h(p) &= E\{\phi(X)\} \\ &= E\{X_i \phi(1_i, X) + (1 - X_i) \phi(0_i, X)\} \\ &= p_i h(1_i, p) + (1 - p_i) h(0_i, p) \end{aligned} \quad (32)$$

where independence applies since $\phi(1_i, X)$ and $\phi(0_i, X)$ are functions of $X_1, \dots, X_{i-1}, X_{i+1}, \dots, X_n$ only.

Theorem 2 *The reliability function $h(p)$ of a coherent system in n components is strictly increasing in each p_i for all $p \in (0, 1)^n$.*

Proof From the pivotal decomposition,

$$\begin{aligned} \frac{\partial h(p)}{\partial p_i} &= h(1_i, p) - h(0_i, p) \\ &= E\{\phi(1_i, X) - \phi(0_i, X)\} \end{aligned} \quad (33)$$

Since ϕ is monotone, $\phi(1_i, x) \geq \phi(0_i, x)$ for all x . So

$$\frac{\partial h(p)}{\partial p_i} \geq 0 \quad (34)$$

Since each component is relevant, there exists a case x^* such that $\phi(1_i, x^*) > \phi(0_i, x^*)$. At each $p \in (0, 1)^n$,

$$P\{X = x^*\} = \prod_{i=1}^n p_i^{x_i^*} (1 - p_i)^{1-x_i^*} > 0 \quad (35)$$

So

$$\frac{\partial h(p)}{\partial p_i} > 0, \text{ for all } p \in (0, 1)^n \quad (36)$$

Each working component is beneficial to the system, so an increased probability of a component working necessarily increases the probability that the system works.

The Signature of a Coherent System

We now consider system reliability as a function of time t . Let $T_1, \dots, T_n$ denote the lifetimes of components $c_1, \dots, c_n$, respectively. Assume that component lifetimes are independent and identically distributed with cumulative probability function $F(t) = P\{T_i \leq t\}$ and survival function

$$\overline{F}(t) = P\{T_i > t\} \quad (37)$$

At time t , component c_i works if and only if its lifetime surpasses t . So

$$[X_i = 1] \iff [T_i > t] \quad (38)$$

and $p_i = \overline{F}(t)$ for $i = 1, \dots, n$.

Let T denote the lifetime of a coherent system with structure function ϕ . At time t , the system works when system's lifetime surpasses t . So

$$[\phi(X) = 1] \iff [T > t] \quad (39)$$

Thus, the survival function for the system is

$$\begin{aligned} \overline{F}_T(t) &= P\{T > t\} \\ &= P\{\phi(X) = 1\} \\ &= h(p_1, \dots, p_n) \\ &= h(\overline{F}(t), \dots, \overline{F}(t)) \end{aligned} \quad (40)$$

Let $T_{(1)} \leq T_{(2)} \leq \dots \leq T_{(n)}$ denote the ordered component lifetimes. From the distribution theory for order statistics,

$$P\{T_{(k)} > t\} = \sum_{j=0}^{k-1} \binom{n}{j} (F(t))^j (\overline{F}(t))^{n-j} \quad (41)$$

Let $\pi_k = \Pr\{T = T_{(k)}\}$ be the probability that the system fails at the k th failure of a component. Define the *signature* of a coherent system as the probability vector $\pi = (\pi_1, \dots, \pi_n)$. The survival function for a coherent system can be written in terms of its signature. Write

$$\begin{aligned} \overline{F}_T(t) &= \sum_{k=1}^n P\{T = T_{(k)}\} \cdot P\{T > t \mid T = T_{(k)}\} \\ &= \sum_{k=1}^n \pi_k P\{T_{(k)} > t\} \\ &= \sum_{k=1}^n \sum_{j=0}^{k-1} \pi_k \binom{n}{j} (F(t))^j (\overline{F}(t))^{n-j} \end{aligned} \quad (42)$$

4 Coherent Systems

Consider the five coherent systems with structure functions given in equations (16–20). For the series system, $\pi(\phi_1) = (1, 0, 0)$ since a series system always fails at the first failure of a component. For the parallel system, $\pi(\phi_2) = (0, 0, 1)$ since a parallel system does not fail until the last failure of a component. A 2-out-of-3 system always fails upon the second failure of a component so that $\pi(\phi_3) = (0, 1, 0)$.

There are $n!$ permutations for the orderings of component failures. We can use Table 1 to calculate the **signatures** for the three-component coherent systems ϕ_4 and ϕ_5 .

So $\pi(\phi_4) = (0, \frac{2}{3}, \frac{1}{3})$ and $\pi(\phi_5) = (\frac{1}{3}, \frac{2}{3}, 0)$.

The signature leads to a method for comparison of two coherent systems. Let π_A and π_B denote the signatures of systems A and B , respectively, where each system has n components. Let T_A and T_B denote the lifetimes of the two systems. Let $\bar{F}_A(t) = \Pr\{T_A > t\}$ and $\bar{F}_B(t) = \Pr\{T_B > t\}$. Define

$$T_A \leq^{st} T_B \quad (43)$$

if and only if

$$\bar{F}_A(t) \leq \bar{F}_B(t), \text{ for all } t \geq 0 \quad (44)$$

That is, system A lifetime is stochastically less than or equal to system B lifetime if and only if the probability of survival beyond any time t is never greater for system A than for system B .

Define

$$\pi_A \leq^{st} \pi_B \quad (45)$$

if and only if

$$\sum_{k=j}^n \pi_{Ak} \leq \sum_{k=j}^n \pi_{Bk}, \text{ for all } j = 1, \dots, n \quad (46)$$

Theorem 3 $\pi_A \leq^{st} \pi_B$ implies $T_A \leq^{st} T_B$.

Table 1 Ordered component failures

$T_{(1)} < T_{(2)} < T_{(3)}$	$T(\phi_4)$	$T(\phi_5)$
$T_1 < T_2 < T_3$	$T_{(2)}$	$T_{(1)}$
$T_1 < T_3 < T_2$	$T_{(2)}$	$T_{(1)}$
$T_2 < T_1 < T_3$	$T_{(2)}$	$T_{(2)}$
$T_2 < T_3 < T_1$	$T_{(3)}$	$T_{(2)}$
$T_3 < T_1 < T_2$	$T_{(2)}$	$T_{(2)}$
$T_3 < T_2 < T_1$	$T_{(3)}$	$T_{(2)}$

Proof Suppose $\pi_A \leq^{st} \pi_B$. From equation (42),

$$\begin{aligned} \bar{F}_A(t) &= \sum_{k=1}^n \sum_{j=0}^{k-1} \pi_{Ak} \binom{n}{j} (F(t))^j (\bar{F}(t))^{n-j} \\ &= \sum_{j=0}^{n-1} \left(\sum_{k=j+1}^n \pi_{Ak} \right) \binom{n}{j} (F(t))^j (\bar{F}(t))^{n-j} \\ &\leq \sum_{j=0}^{n-1} \left(\sum_{k=j+1}^n \pi_{Bk} \right) \binom{n}{j} (F(t))^j (\bar{F}(t))^{n-j} \\ &= \sum_{k=1}^n \sum_{j=0}^{k-1} \pi_{Bk} \binom{n}{j} (F(t))^j (\bar{F}(t))^{n-j} \\ &= \bar{F}_B(t) \end{aligned} \quad (47)$$

Thus, $T_A \leq^{st} T_B$.

Not all pairs of coherent systems have signatures that are comparable by the signature criterion. Consider, for example, the four-component coherent systems with structure functions

$$\phi_A(x) = x_1 \left(x_2 \coprod x_3 \coprod x_4 \right) \quad (48)$$

and

$$\phi_B(x) = (x_1 x_2) \coprod (x_3 x_4) \quad (49)$$

One can easily derive $\pi_A = (\frac{1}{4}, \frac{1}{4}, \frac{1}{2}, 0)$ and $\pi_B = (0, \frac{2}{3}, \frac{1}{3}, 0)$. So,

$$\pi_{A3} + \pi_{A4} > \pi_{B3} + \pi_{B4} \quad (50)$$

but

$$\pi_{A2} + \pi_{A3} + \pi_{A4} < \pi_{B2} + \pi_{B3} + \pi_{B4} \quad (51)$$

However, the coherent systems of three components can be compared and ordered by the signature criterion as

$$T(\phi_2) \leq^{st} T(\phi_5) \leq^{st} T(\phi_3) \leq^{st} T(\phi_4) \leq^{st} T(\phi_1) \quad (52)$$

For the 20 systems of four components, there are $\binom{20}{2} = 190$ possible comparisons. In 180 of these cases, a stochastic inequality can be implied from the signature criterion.

Parallel, Series, and Series-Parallel Systems

Introduction

In the area of reliability, often the objective is to determine the probability that a system will function for a certain period. Such systems consist of multiple components connected according to a certain structure. Whether a system functions depends on how the components are connected as well as the state of each component. Each component will have a state that can be classified as either “functioning” or “failed”. In most cases, there is an underlying probability distribution that is used to determine if the component is in the functioning state or the failed state at some time t .

Three important system configurations that are widely used in reliability are series systems, parallel systems, and series-parallel systems. In a series system, components are connected in such a way that the failure of a single component results in system failure. A series system is also referred to as a **competing risks system** since the failure of an individual (system) can be classified as one of n possible risks (component) that competes for the individual’s failure. An example of a series system is illustrated in Agustin and Peña [1] where a series system of softwares is considered with the failure of a software (component) resulting in the failure of the system. On the other hand, a system where the failure of all components will result in the failure of the system is called a *parallel system*. Some papers that have considered parallel systems include Kvam and Peña [2] on an equal load-sharing dynamic model and Sinkovic *et al.* [3] in the area of communication. A common interest in the aforementioned papers is in modeling how the load can be shared by the components in parallel whenever critical jobs or tasks are given to the system to complete. In addition, standby or redundant systems can also be associated with parallel systems (see Osaki and Nakagawa [4]). For such systems, the operational unit can be considered to be connected in parallel with all the standby units. As soon the unit fails, one of the standby units goes into operation. Finally, a series-parallel system is a system in which m subsystems are connected in series and

each subsystem consists of k components connected in parallel (see Baxter and Harche [5]). For such a system, failure is observed if a subsystem has failed. Note that the failure of a subsystem occurs when all of the k components have failed, hence the name *series-parallel system*.

One of the goals in reliability is to ensure that at any given instant, we observe a functioning system with a high probability. The probability that the system is functioning is defined as the system reliability. In this article, we will obtain the system reliability for the series, parallel, and series-parallel systems. The system reliability will depend on the reliability of each component as well as on how the components are connected. Moreover, we will assume that the reliability of each component is a function of how long it is observed. The time to failure of a component will depend on a known probability distribution.

System Reliability

Structure Function

Consider a system of n components in which a component is either in a “functioning” state or in a “failed” state. For $i = 1, \dots, n$, let X_i be the binary random variable defined to be

$$X_i = \begin{cases} 1, & \text{component } i \text{ is functioning} \\ 0, & \text{otherwise} \end{cases} \quad (1)$$

The random variables $X_1, \dots, X_n$ are assumed to be independent. Thus, the components function independent of one another. We will define $\mathbf{X} = (X_1, \dots, X_n)$ to be the state vector of the system. The state of the system depends on a function that considers how the components are connected as well as the corresponding state of each component. This is called the *structure function* of the system and is denoted by $\phi(\mathbf{X})$. The function $\phi(\mathbf{X})$ is a binary random variable where

$$\phi(\mathbf{X}) = \begin{cases} 1, & \text{system is functioning} \\ 0, & \text{otherwise} \end{cases} \quad (2)$$

To describe the systems of interest in this article, we need to define the following: vector inequality, relevant components, and a nondecreasing structure function.

Definition Let $\mathbf{X} \in \mathbf{R}^n$ and $\mathbf{Y} \in \mathbf{R}^n$ be two state vectors.

2 Parallel, Series, and Series-Parallel Systems

1. We say that $X \leq Y$ if $X_i \leq Y_i$ for all $i = 1, \dots, n$. We have $X < Y$ if $X_j < Y_j$ for at least one j .
2. Component i is irrelevant if for all values of X_j , where $j = 1, \dots, n$ and $j \neq i$,

$$\begin{aligned} &\phi(X_1, \dots, X_{i-1}, 0, X_{i+1}, \dots, X_n) \\ &= \phi(X_1, \dots, X_{i-1}, 1, X_{i+1}, \dots, X_n) \end{aligned} \quad (3)$$

3. A structure function is a nondecreasing function if $X \leq Y$ implies that $\phi(X) \leq \phi(Y)$.

The primary interest in reliability are systems where replacing a failed component by a functioning component does not result in the system being “worse off”. In other words, the structure function of the system is nondecreasing. Such a system is called a *coherent system* (see **Coherent Systems**).

Definition A system of n components where all components are relevant and whose structure function is nondecreasing is called a *coherent system*.

In what follows, we will show that a series system, a parallel system, and a series-parallel system are all examples of coherent systems.

Series System. A series system is defined to be a system that functions if and only if all components are functioning. One can also consider such a system as having failed as soon as one component has failed. Thus, the structure function of a series system is

$$\phi(X) = X_1 X_2 \dots X_n = \prod_{i=1}^n X_i \quad (4)$$

Since the random variables $X_1, \dots, X_n$ are all binary, the structure function of a series system can be written as $\phi(X) = \min(X_1, \dots, X_n)$. Figure 1 illustrates a series system with three components.

As an illustration, consider a series system where component 1 has failed while the remaining $n - 1$ components are functioning. Thus, the state vector is

Figure 1 Diagram for a series system with three components

$X = (X_1, X_2, \dots, X_n) = (0, 1, \dots, 1)$, which results in $\phi(X) = \min(0, 1, \dots, 1) = 0$. On the other hand, if all components are functioning, then $\phi(X) = \min(1, \dots, 1) = 1$. Clearly, $\phi(X) = 0$ whenever $X_i = 0$ for some i . Thus, to show that a series system is a coherent system, we need to consider two state vectors X and Y such that $X_i = 0$ for some $i = 1, \dots, n$ while $Y_j = 1$ for all $j = 1, \dots, n$. Thus, $X < Y$ implies that $\phi(X) \leq \phi(Y)$, which means that ϕ is nondecreasing. In addition, it is easily seen that a series system with state vector $Y = (1, 1, \dots, 1)$ will fail as soon as one component fails. Hence, each component in a series system is relevant. It follows that a series system is coherent.

Parallel System. A parallel system is a system that functions if and only if at least one component is functioning. Since $1 - X_j = 0$ whenever component j has failed, the structure function of a parallel system is

$$\begin{aligned} \phi(X) &= 1 - (1 - X_1) \dots (1 - X_n) \\ &= 1 - \prod_{i=1}^n (1 - X_i) \end{aligned} \quad (5)$$

It should be noted that an alternative way of expressing the structure function of a parallel system is $\phi(X) = \max(X_1, \dots, X_n)$. Figure 2 presents a diagram for a parallel system with two components.

To illustrate, suppose that all components have failed except for component 1. Thus, $X_1 = 1$ while $X_2 = 0, \dots, X_n = 0$. It follows that $\phi(X) = \max(1, 0, \dots, 0) = 1$. On the other hand, if $X_1 = 0, \dots, X_n = 0$, then $\phi(X) = \max(0, \dots, 0) = 0$. To show that a parallel system is coherent, it suffices to consider two state vectors X and Y such that $X_j = 0$ for all $j = 1, \dots, n$ and $Y_i = 1$ for some $i = 1, \dots, n$. Clearly, $X < Y$ and it follows that $\phi(X) < \phi(Y)$. Moreover, every component is relevant since the structure function is equal to zero whenever all components have failed whereas the structure function is one if the state of one component changes its state from failed to functioning. Hence, a parallel system is coherent.

Series-Parallel System. We define a series-parallel system with mk components as a system comprised of m subsystems connected in series. Each subsystem consists of k components connected in

Figure 2 Diagram for a parallel system with two components

parallel. Thus, if at least one component in each subsystem is functioning, then the system is functioning. On the other hand, if all components in one subsystem have failed, then the system has failed regardless of the state of the components in the other subsystems. To obtain the structure function of a series-parallel system, let us define the structure function of the j th subsystem to be $\phi_j(X_j)$, for $j = 1, \dots, m$. The vector $X_j = (X_{j1}, \dots, X_{jk})$ represents the state vector of the j th subsystem, where X_{jl} is the random variable that represents the state of the l th component in the subsystem, for $l = 1, \dots, k$. One can obtain

$$\phi_j(X_j) = 1 - \prod_{l=1}^k (1 - X_{jl}) = \max(X_{j1}, \dots, X_{jk}) \quad (6)$$

Hence, by setting $X = (X_1, \dots, X_m)$, the structure function of the series-parallel system is

$$\phi(X) = \prod_{j=1}^m \phi_j(X_j) = \prod_{j=1}^m \left[1 - \prod_{l=1}^k (1 - X_{jl}) \right] \quad (7)$$

An alternative form for the structure function of the series-parallel system is

$$\phi(X) = \min_{1 \leq j \leq m} \left[\max_{1 \leq l \leq k} X_{jl} \right] \quad (8)$$

To provide an illustration of a series-parallel system, consider a series-parallel system with $m = 3$ subsystems with each subsystem containing $k = 2$ components. Hence, the system has a total of six components. An illustration for this system is given in Figure 3. For example, suppose that $X_{11} = 0$, $X_{12} = 0$, and $X_{22} = 0$ while the remaining X_{jl} are all equal to 1. One can easily see that subsystem 1 has failed while the remaining subsystems are still functioning. It follows that

$$\phi_1(X_{11}, X_{12}) = \max(0, 0) = 0 \quad (9)$$

$$\phi_2(X_{21}, X_{22}) = \max(1, 0) = 1 \quad (10)$$

$$\phi_3(X_{31}, X_{32}) = \max(1, 1) = 1 \quad (11)$$

which results in $\phi(X) = \min(0, 1, 1) = 0$. To show that a series-parallel system is coherent, consider a state vector Y such that all subsystems are functioning. In other words, for all $j = 1, \dots, m$, there exists a component, denoted by l , such that $Y_{jl} = 1$. In addition, consider a state vector X such that there exists a subsystem j where $X_{j1} = \dots = X_{jk} = 0$. It follows that $X < Y$ and $\phi(X) < \phi(Y)$. Moreover, the relevance of each component follows from the fact that components in series systems and parallel systems are all relevant.

System Reliability

Let $p_i = P\{X_i = 1\}$ be the probability that the i th component is functioning and suppose $\mathbf{p} = (p_1, \dots, p_n)$. We define

Figure 3 Diagram for a series-parallel system with $m = 3$ subsystems and $k = 2$ components per subsystem

4 Parallel, Series, and Series-Parallel Systems

$$h(\mathbf{p}) = E[\phi(X)] = P\{\phi(X) = 1\} \quad (12)$$

to be the reliability of the system. Recall that $X_1, \dots, X_n$ are independent random variables. Thus, for a series system, the reliability of the system is

$$\begin{aligned} h(\mathbf{p}) &= P\{X_1 = 1, \dots, X_n = 1\} \\ &= P\{X_1 = 1\} \dots P\{X_n = 1\} = \prod_{i=1}^n p_i \end{aligned} \quad (13)$$

On the other hand, to find the reliability of a parallel system, it is more convenient to write the reliability as

$$h(\mathbf{p}) = 1 - P\{\phi(X) = 0\} \quad (14)$$

By the independence of the X_i 's, we get

$$\begin{aligned} h(\mathbf{p}) &= 1 - P\{X_1 = 0, \dots, X_n = 0\} \\ &= 1 - P\{X_1 = 0\} \dots P\{X_n = 0\} \end{aligned} \quad (15)$$

It follows that the reliability of a parallel system is

$$\begin{aligned} h(\mathbf{p}) &= 1 - [1 - P\{X_1 = 1\}] \dots [1 - P\{X_n = 1\}] \\ &= 1 - \prod_{i=1}^n [1 - p_i] \end{aligned} \quad (16)$$

For a series-parallel system, we first define for $j = 1, \dots, m$ and $l = 1, \dots, k$, $p_{jl} = P\{X_{jl} = 1\}$ to be the probability that the l th component in the j th subsystem is functioning. We will set $\mathbf{p} = (\mathbf{p}_1, \dots, \mathbf{p}_m)$ where $\mathbf{p}_j = (p_{j1}, \dots, p_{jk})$. Since the subsystems are connected in series, it follows from equation (13) that

$$\begin{aligned} h(\mathbf{p}) &= P\{\phi_1(X_1) = 1, \dots, \phi_m(X_m) = 1\} \\ &= \prod_{j=1}^m P\{\phi_j(X_j) = 1\} \end{aligned} \quad (17)$$

Since the components in a subsystem are connected in parallel, we use equation (16) to show that

$$P\{\phi_j(X_j) = 1\} = 1 - \prod_{l=1}^k (1 - p_{jl}) \quad (18)$$

Thus, the reliability of a series-parallel system is

$$\begin{aligned} h(\mathbf{p}) &= \left[1 - \prod_{l=1}^k (1 - p_{1l}) \right] \dots \left[1 - \prod_{l=1}^k (1 - p_{ml}) \right] \\ &= \prod_{j=1}^m \left[1 - \prod_{l=1}^k (1 - p_{jl}) \right] \end{aligned} \quad (19)$$

Time-Dependent System Reliability

In this section, we will consider a system of components where the lifetime of the i th component is a random variable Y_i . For example, a car (system) will have parts (components) such as the wheel, engine, or air conditioning system where the time to failure of each part is a random variable that depends on a number of factors (e.g., driving conditions, manufacturing process of the part, etc.) We will assume that the components operate independently of one another. In other words, the component lifetime variables $Y_1, Y_2, \dots, Y_n$ are independent. Our main interest is to obtain the system reliability on the basis of the underlying assumption on the distribution of the component lifetimes. In doing so, we need to provide the appropriate representation of the distribution of the lifetime of a system. Leemis [6] provides an extensive discussion on five functions that are typically used in reliability. We will focus on three of these functions, namely, the probability density function, the survivor function, and the hazard function.

Let Y_i be a random variable with **probability density function** $f_i(y; \theta)$ and cumulative distribution function $F_i(y; \theta) = P\{Y_i \leq y\}$, for $i = 1, \dots, n$ and some parameter θ . It follows that the reliability of component i is

$$\begin{aligned} S_i(y; \theta) &\equiv P\{Y_i > y\} = \int_y^\infty f_i(u; \theta) du \\ &= 1 - F_i(y; \theta) \end{aligned} \quad (20)$$

The reliability of component i given in equation (20) is also known as the survivor function of Y_i . Since $F_i(y; \theta) = \int_0^y f_i(t; \theta) dt$, the density function of the i th component, in terms of the reliability of component i , is

$$f_i(y; \theta) = -\frac{d}{dy} S_i(y; \theta) = -S'_i(y; \theta) \quad (21)$$

Another representation for the lifetime of a component is *via* the hazard function $h_i(y; \theta)$. This is especially important due to its interpretation as the amount of risk associated with a component. In terms of the **component reliability**, the hazard function can be expressed as

$$\begin{aligned} h_i(y; \theta) &= \lim_{\Delta y \searrow 0} \frac{S_i(y; \theta) - S_i(y + \Delta y; \theta)}{S_i(y; \theta) \Delta y} \\ &= -\frac{S'_i(y; \theta)}{S_i(y; \theta)} = \frac{f_i(y; \theta)}{S_i(y; \theta)} \end{aligned} \quad (22)$$

Let Y be the random variable associated with the system lifetime and $S(y; \theta)$ be the system reliability. The corresponding density function, cumulative distribution function, and hazard function of the system lifetime are $f(y; \theta)$, $F(y; \theta)$, and $h(y; \theta)$, respectively. In terms of the density function and cumulative distribution function, the hazard function is of the form

$$h(y; \theta) = \frac{f(y; \theta)}{S(y; \theta)} \quad (23)$$

Our main interest is to obtain the appropriate expressions for the series, parallel, and series-parallel systems.

For a series system, note that the system lifetime can be expressed as $Y = \min(Y_1, \dots, Y_n)$. This results in a system reliability equal to

$$\begin{aligned} S(y; \theta) &= P\{Y > y\} = P\{\min(Y_1, \dots, Y_n) > y\} \\ &= P\{Y_1 > y, \dots, Y_n > y\} \end{aligned} \quad (24)$$

Since the component lifetimes are assumed to be independent, the system reliability simplifies to

$$S(y; \theta) = \prod_{i=1}^n P\{Y_i > y\} = \prod_{i=1}^n S_i(y; \theta) \quad (25)$$

Following equation (21), the density function of Y is obtained as

$$f(y; \theta) = -\sum_{i=1}^n S'_i(y; \theta) \prod_{\substack{j=1 \\ j \neq i}}^n S_j(y; \theta) \quad (26)$$

The hazard function for a series system is obtained by substituting the system reliability given in equation (25) and the density function given in equation (26) into equation (23).

For a parallel system, the random variable Y can be expressed as $Y = \max(Y_1, \dots, Y_n)$. It follows that the system reliability for a parallel system is

$$\begin{aligned} S(y; \theta) &= P\{\max(Y_1, \dots, Y_n) > y\} \\ &= 1 - P\{\max(Y_1, \dots, Y_n) \leq y\} \\ &= 1 - P\{Y_1 \leq y, \dots, Y_n \leq y\} \end{aligned} \quad (27)$$

By the independence of the component lifetimes, the resulting system reliability is

$$S(y; \theta) = 1 - \prod_{i=1}^n P\{Y_i \leq y\} = 1 - \prod_{i=1}^n [1 - S_i(y; \theta)] \quad (28)$$

The corresponding density function for the parallel system is

$$f(y; \theta) = -\sum_{i=1}^n S'_i(y; \theta) \prod_{\substack{j=1 \\ j \neq i}}^n [1 - S_j(y; \theta)] \quad (29)$$

For a series-parallel system with m subsystems connected in series with each subsystem containing k components connected in parallel, let Y_j be the lifetime of the j th subsystem. The random variable Y_{jl} denotes the lifetime of the l th component in the j th subsystem, for $j = 1, \dots, m$ and $l = 1, \dots, k$. Since the components are all independent, it follows that the subsystem lifetimes are also independent. By following the same arguments used to obtain equation (25), it follows that

$$S(y; \theta) = P\{Y > y\} = \prod_{j=1}^m P\{Y_j > y\} \quad (30)$$

Since $P\{Y_j \leq y\} = P\{\max(Y_{j1}, \dots, Y_{jk}) \leq y\}$, we can apply equation (28) for each subsystem to obtain the system reliability. Thus, after straightforward computations, equation (30) simplifies to

$$\begin{aligned} S(y; \theta) &= \prod_{j=1}^m \left[1 - \prod_{l=1}^k P\{Y_{jl} \leq y\} \right] \\ &= \prod_{j=1}^m \left[1 - \prod_{l=1}^k [1 - S_{jl}(y; \theta)] \right] \end{aligned} \quad (31)$$

6 Parallel, Series, and Series-Parallel Systems

From equation (31), the density function of Y for the series-parallel system is

$$f(y; \theta) = - \sum_{j=1}^m \left[\sum_{l=1}^k S'_{jl}(y; \theta) \prod_{\substack{l^*=1 \\ l^* \neq l}}^k [1 - S_{jl^*}(y; \theta)] \right] \times \left[\prod_{\substack{j^*=1 \\ j^* \neq j}}^m \left(1 - \prod_{l=1}^k (1 - S_{j^*l}(y; \theta)) \right) \right] \quad (32)$$

Example As an illustration, consider the case when each component lifetime follows an exponential distribution with mean $\theta = \lambda_i$, that is, $Y_i \sim \exp(\lambda_i)$. In other words, the random variable Y_i has density function

$$f_i(y; \lambda_i) = \frac{1}{\lambda_i} \exp\left(-\frac{y}{\lambda_i}\right), \quad y > 0 \quad (33)$$

Using equation (20), the survivor function of Y_i is

$$\begin{aligned} S_i(y; \lambda_i) &= \int_y^\infty \frac{1}{\lambda_i} \exp\left(-\frac{u}{\lambda_i}\right) du \\ &= \exp\left(-\frac{y}{\lambda_i}\right), \quad y > 0 \end{aligned} \quad (34)$$

while the hazard function is

$$h_i(y; \lambda_i) = \frac{f_i(y; \lambda_i)}{S_i(y; \lambda_i)} = \frac{1}{\lambda_i}, \quad y > 0 \quad (35)$$

Let $\lambda = (\lambda_1, \dots, \lambda_n)$ be the parameter vector of interest. For a series system with n components, equation (25) simplifies to

$$S(y; \lambda) = \prod_{i=1}^n \exp\left(-\frac{y}{\lambda_i}\right) = \exp\left(-y \sum_{i=1}^n \frac{1}{\lambda_i}\right) \quad (36)$$

Since the density function of Y is

$$\begin{aligned} f(y; \lambda) &= -\frac{d}{dy} S(y; \lambda) = \left(\sum_{i=1}^n \frac{1}{\lambda_i} \right) \\ &\times \exp\left(-y \sum_{j=1}^n \frac{1}{\lambda_j}\right) \end{aligned} \quad (37)$$

it follows that for a series system, the random variable Y is exponentially distributed with mean $[\sum_{i=1}^n (\lambda_i)^{-1}]^{-1}$. It can be easily seen that by using equation (23), the hazard function is

$$h(y; \lambda) = \sum_{i=1}^n \frac{1}{\lambda_i} \quad (38)$$

On the other hand, for a parallel system, using the survivor function of an exponential random variable given in equation (34) in equation (28) results in a system reliability equal to

$$S(y; \lambda) = 1 - \prod_{i=1}^n \left[1 - \exp\left(-\frac{y}{\lambda_i}\right) \right], \quad y > 0 \quad (39)$$

The resulting density function of the system lifetime for a parallel system is

$$\begin{aligned} f(y; \lambda) &= -\frac{d}{dy} S(y; \lambda) \\ &= \frac{d}{dy} \left[\prod_{i=1}^n \left(1 - \exp\left(-\frac{y}{\lambda_i}\right) \right) \right] \\ &= \sum_{i=1}^n \left(\frac{1}{\lambda_i} \right) \exp\left(-\frac{y}{\lambda_i}\right) \\ &\times \left[\prod_{\substack{j=1 \\ j \neq i}}^n \left(1 - \exp\left(-\frac{y}{\lambda_j}\right) \right) \right] \end{aligned} \quad (40)$$

This can also be obtained by replacing the appropriate expressions in equation (29) by the survivor function of an exponential random variable given in equation (34).

Finally, for a series-parallel system, let λ_{jl} be the mean lifetime of the l th component in the j th subsystem, for $j = 1, \dots, m$ and $l = 1, \dots, k$. The parameter vector of interest is $\lambda = (\lambda_{11}, \dots, \lambda_{1k}, \lambda_{21}, \dots, \lambda_{2k}, \dots, \lambda_{m1}, \dots, \lambda_{mk})$. Equation (31) simplifies to

$$S(y; \lambda) = \prod_{j=1}^m \left[1 - \prod_{l=1}^k \left(1 - \exp\left(-\frac{y}{\lambda_{jl}}\right) \right) \right], \quad y > 0 \quad (41)$$

Using equations (32) and (34), the density function of Y for the series-parallel system is

$$f(y; \lambda) = -\frac{d}{dy} S(y; \lambda)$$

$$\begin{aligned}
 &= \sum_{j=1}^m \left\{ \left[\prod_{\substack{j^*=1 \\ j^* \neq j}}^m \left(1 - \prod_{l=1}^k \left(1 - \exp \left(-\frac{y}{\lambda_{jl^*}} \right) \right) \right) \right] \right. \\
 &\quad \times \left[\sum_{l=1}^k \left(\prod_{\substack{l^*=1 \\ l^* \neq l}}^k \left(1 - \exp \left(-\frac{y}{\lambda_{jl^*}} \right) \right) \right) \right] \\
 &\quad \left. \times \left(\frac{1}{\lambda_{jl}} \right) \exp \left(-\frac{y}{\lambda_{jl}} \right) \right\} \quad (42)
 \end{aligned}$$

As a special case, suppose $Y_i \sim \exp(\alpha)$ for all $i = 1, \dots, n$. For ease of notation, we will let α be the parameter of interest. The system reliability of a series system simplifies to

$$S(y; \alpha) = \exp \left(-\frac{n}{\alpha} y \right) = \exp \left(-\frac{y}{\alpha/n} \right), \quad y > 0 \quad (43)$$

which shows that the system lifetime Y is exponentially distributed with mean α/n . On the other hand, the system reliability of a parallel system can be written as

$$S(y; \alpha) = 1 - \left[1 - \exp \left(-\frac{y}{\alpha} \right) \right]^n, \quad y > 0 \quad (44)$$

while the system reliability of a series-parallel system simplifies to

$$S(y; \alpha) = \left[1 - \left(1 - \exp \left(-\frac{y}{\alpha} \right) \right)^k \right]^m, \quad y > 0 \quad (45)$$

The appropriate density function for each system can then be obtained by differentiating the corresponding system reliability.

Example Whenever the risk of failure rapidly increases with time, a failure time distribution that is commonly used is the Weibull distribution. For instance, Ferdous *et al.* [7] assumed **software failure** times that follow the Weibull distribution. Their goal was to predict failure rates and mean time to failure of the software.

In this example, we consider the case where the lifetime for component i follows a Weibull distribution with parameters α_i and β_i . Hence, the

random variable Y_i has density function

$$f_i(y; \alpha_i, \beta_i) = \frac{\beta_i}{\alpha_i} \left(\frac{y}{\alpha_i} \right)^{\beta_i-1} \exp \left[-\left(\frac{y}{\alpha_i} \right)^{\beta_i} \right], \quad y > 0 \quad (46)$$

It is easily seen that $\beta_i = 1$ will result in $Y_i \sim \exp(\alpha_i)$. The survivor function of Y_i is

$$\begin{aligned}
 S_i(y; \alpha_i, \beta_i) &= \int_y^\infty \frac{\beta_i}{\alpha_i} \left(\frac{u}{\alpha_i} \right)^{\beta_i-1} \exp \left[-\left(\frac{u}{\alpha_i} \right)^{\beta_i} \right] du \\
 &= \exp \left[-\left(\frac{y}{\alpha_i} \right)^{\beta_i} \right], \quad y > 0 \quad (47)
 \end{aligned}$$

while the hazard function is

$$h_i(y; \alpha_i, \beta_i) = \frac{\beta_i}{\alpha_i} \left(\frac{y}{\alpha_i} \right)^{\beta_i-1}, \quad y > 0 \quad (48)$$

Let $\alpha = (\alpha_1, \dots, \alpha_n)$ and $\beta = (\beta_1, \dots, \beta_n)$ denote the two parameter vectors of interest. For a series system, the system reliability is

$$\begin{aligned}
 S(y; \alpha, \beta) &= \prod_{i=1}^n \exp \left[-\left(\frac{y}{\alpha_i} \right)^{\beta_i} \right] \\
 &= \exp \left[-\sum_{i=1}^n \left(\frac{y}{\alpha_i} \right)^{\beta_i} \right], \quad y > 0 \quad (49)
 \end{aligned}$$

In the special case where $\alpha_i = \alpha$ and $\beta_i = \beta$ for $i = 1, \dots, n$, equation (49) simplifies to

$$\begin{aligned}
 S(y; \alpha, \beta) &= \exp \left[-\sum_{i=1}^n \left(\frac{y}{\alpha} \right)^{\beta} \right] = \exp \left[-n \left(\frac{y}{\alpha} \right)^{\beta} \right] \\
 &= \exp \left[-\left(\frac{n^{1/\beta} y}{\alpha} \right)^{\beta} \right], \quad y > 0 \quad (50)
 \end{aligned}$$

which implies that Y is a Weibull random variable with parameters $\alpha/(n^{1/\beta})$ and β . On the other hand, by using equations (28) and (47), the system reliability for a parallel system is

$$S(y; \alpha, \beta) = 1 - \prod_{i=1}^n \left[1 - \exp \left[-\left(\frac{y}{\alpha_i} \right)^{\beta_i} \right] \right], \quad y > 0 \quad (51)$$

8 Parallel, Series, and Series-Parallel Systems

Finally, for a series-parallel system with k components in each of the m subsystems, the system reliability is

$$S(y; \alpha, \beta) = \prod_{j=1}^m \left[1 - \prod_{l=1}^k \left(1 - \exp \left[- \left(\frac{y}{\alpha_{jl}} \right)^{\beta_{jl}} \right] \right) \right], \quad y > 0 \quad (52)$$

***k*-out-of-*n* Systems**

Definition of *k*-out-of-*n* System Model

A system with n components is referred to as an n -component system. Each component is either working or not working (failed). The design of the system determines whether the system as a whole is working. A series system is considered working or “good” if all n components are working. This type of system is seen in decorative tree lights or a high-voltage multicell battery. If one component in a series system fails, then the entire system will fail. A parallel system is a system that will continue to work if at least one of the n components is working. A k -out-of- n system is considered working if at least k out of the n components are working. Examples of this type of system include an airplane with four engines that will work (fly) if at least two of the engines work, a stereo with two speakers that will work (may be heard) if at least one of the two speakers work, or a car with eight cylinders that will work (operate) if at least four of the cylinders are working (firing). A k -out-of- n system may be described in two ways, depending on the definition of the parameter, k , as follows. The parameter k may represent the number of components in the system that must work in order for the entire system to work, referred to as a k -out-of- n :G system. Or k may represent the number of components in the system that must fail before the entire system fails, referred to as a k -out-of- n :F system. The k -out-of- n :F system is equivalent to a $n - (k - 1)$ -out-of- n :G system. The series system and the parallel system are both special cases of a k -out-of- n system with $k = 1$ and $k = n$, respectively, for the k -out-of- n :F system.

Reliability Computations for *k*-out-of-*n* System (Assuming Independent and Identical Components with Known Reliabilities)

When the components are independent and identically distributed (i.i.d.), calculating the reliability of the system is easily done using the binomial distribution. In the context of the k -out-of- n :G system model, the random variable X represents the number of components out of the n components that work and the

probability that each component works is p . In other words, $P(X = x)$ means the probability that exactly x components work out of the n components in the system. The probability mass function of the binomial random variable X is

$$P(X = x) = \binom{n}{x} p^x (1 - p)^{n-x}, \quad x = 0, 1, 2, \dots, n \quad (1)$$

and the cumulative distribution function (CDF) is given by

$$P(X \leq x) = \sum_{i=0}^x P(X = i) \quad (2)$$

The reliability of the k -out-of- n :G system is the probability that at least k out of the n components work and is given as

$$P(X \geq k) = R(k, n, p) = \sum_{i=k}^n \binom{n}{i} p^i (1 - p)^{n-i} \quad (3)$$

where n is the number of components, p is the reliability of each component, and k is the minimum number of components that need to work for the system to work. The reliability of the system may be written as a function of the CDF, that is,

$$\begin{aligned} R(k, n, p) &= \sum_{i=k}^n \binom{n}{i} p^i (1 - p)^{n-i} \\ &= 1 - P(X \leq k - 1) \end{aligned} \quad (4)$$

The reliability of the system changes as the parameters n , p , and k change. If two of the parameters are fixed and the remaining parameter changes, the reliability of the system changes as follows:

- If p and k remain fixed, the reliability of the system increases as n increases.
- If p and n remain fixed, the reliability of the system decreases as k increases.
- If n and k remain fixed, the reliability of the system increases as p increases.

The changes in the reliability of the system can be shown for each case described above. The increase in reliability of the system for a unit increase in n can be found by calculating the difference

2 k -out-of- n Systems

$R(k, n, p) - R(k, n - 1, p)$. To derive an expression for the difference, Kuo and Zuo [1] show that pivotal decomposition to component n may be used as follows:

$$\begin{aligned}
 R(k, n, p) &= R(k - 1, n - 1, p)p + R(k, n - 1, p)(1 - p) \\
 &= P(\text{at least } k - 1 \text{ components work out of } n - 1 \text{ components}) P(\text{the } n\text{th component works}) + P(\text{at least } k \text{ components work out of } n - 1 \text{ components}) P(\text{the } n\text{th component fails}) \\
 &= \sum_{i=k-1}^{n-1} \left\{ \binom{n-1}{i} p^i (1-p)^{(n-1)-i} \right\} p \\
 &\quad + \sum_{i=k}^{n-1} \left\{ \binom{n-1}{i} p^i (1-p)^{(n-1)-i} \right\} (1-p) \\
 &= \sum_{i=k-1}^{n-1} \left\{ \binom{n-1}{i} p^i (1-p)^{(n-1)-i} \right\} p \\
 &\quad - \sum_{i=k}^{n-1} \left\{ \binom{n-1}{i} p^i (1-p)^{(n-1)-i} \right\} p \\
 &\quad + \sum_{i=k}^{n-1} \left\{ \binom{n-1}{i} p^i (1-p)^{(n-1)-i} \right\} \\
 &= \binom{n-1}{k-1} p^k (1-p)^{n-k} \\
 &\quad + \sum_{i=k}^{n-1} \left\{ \binom{n-1}{i} p^i (1-p)^{(n-1)-i} \right\} p \\
 &\quad - \sum_{i=k}^{n-1} \left\{ \binom{n-1}{i} p^i (1-p)^{(n-1)-i} \right\} p \\
 &\quad + \sum_{i=k}^{n-1} \left\{ \binom{n-1}{i} p^i (1-p)^{(n-1)-i} \right\} \quad (5)
 \end{aligned}$$

The second and third terms cancel and the reliability of the system may be written as,

$$\begin{aligned}
 R(k, n, p) &= \binom{n-1}{k-1} p^k (1-p)^{n-k} \\
 &\quad + \sum_{i=k}^{n-1} \left\{ \binom{n-1}{i} p^i (1-p)^{(n-1)-i} \right\}
 \end{aligned}$$

$$= \binom{n-1}{k-1} p^k (1-p)^{n-k} + R(k, n-1, p) \quad (6)$$

Solving for the difference, $R(k, n, p) - R(k, n - 1, p)$, we see that the increase in the system reliability for an increase of one component is given by

$$\begin{aligned}
 R(k, n, p) - R(k, n - 1, p) &= \binom{n-1}{k-1} p^k (1-p)^{n-k}, \quad n \geq k \quad (7)
 \end{aligned}$$

Notice the difference is positive, meaning that the reliability of the system does increase as n increases, but as n increases, the *amount of improvement* in system reliability decreases.

As the parameter k decreases, the system reliability will increase. This can be shown by computing the difference in a unit decrease in k , $R(k - 1, n, p) - R(k, n, p)$.

$$\begin{aligned}
 R(k - 1, n, p) - R(k, n, p) &= P(\text{at least } k - 1 \text{ components work out of } n) \\
 &\quad - P(\text{at least } k \text{ components work out of } n) \\
 &= P(\text{exactly } k - 1 \text{ components work out of } n) \\
 &= \binom{n}{k-1} p^{k-1} (1-p)^{n-k+1} \quad (8)
 \end{aligned}$$

Therefore, for a unit decrease in k , the reliability of the system increases since the difference $R(k - 1, n, p) - R(k, n, p)$ is positive.

Since the parameter p is continuous, we can take the derivative of the reliability function with respect to p to find how the system reliability changes with respect to the **component reliability** p if the components are i.i.d.

$$\begin{aligned}
 \frac{d}{dp} R(k, n, p) &= \frac{d}{dp} \sum_{i=k}^n \binom{n}{i} p^i (1-p)^{n-i} \\
 &= \frac{d}{dp} \left\{ \binom{n}{k} p^k (1-p)^{n-k} \right. \\
 &\quad + \binom{n}{k+1} p^{k+1} (1-p)^{n-k-1} \\
 &\quad + \binom{n}{k+2} p^{k+2} (1-p)^{n-k-2}
 \end{aligned}$$

$$\begin{aligned}
& + \cdots + \binom{n}{n-1} p^{n-1} (1-p)^{n-(n-1)} \\
& + \binom{n}{n} p^n (1-p)^{n-n} \Big\} \\
= & \binom{n}{k} (-p^k (n-k) (1-p)^{n-k-1} \\
& + kp^{k-1} (1-p)^{n-k}) \\
& + \binom{n}{k+1} (-p^{k+1} (n-k-1) (1-p)^{n-k-2} \\
& + (k+1)p^k (1-p)^{n-k-1}) \\
& + \binom{n}{k+2} (-p^{k+2} (n-k-2) (1-p)^{n-k-3} \\
& + (k+2)p^{k+1} (1-p)^{n-k-2}) + \cdots + \binom{n}{n-1} \\
& \times (-p^{n-1} (n-(n-1)) (1-p)^{n-n} \\
& + (n-1)p^{n-2} (1-p)^{n-(n-1)}) + \binom{n}{n} (np^{n-1}) \\
= & k \binom{n}{k} p^{k-1} (1-p)^{n-k} \\
& + \left\{ (k+1) \binom{n}{k+1} - \binom{n}{k} (n-k) \right\} \\
& \times p^k (1-p)^{n-k-1} \\
& + \left\{ (k+2) \binom{n}{k+2} - \binom{n}{k+1} (n-k-1) \right\} \\
& \times p^{k+1} (1-p)^{n-k-2} \\
& - \binom{n}{k+2} (n-k-2) p^{k+2} (1-p)^{n-k-3} \\
& + \cdots + (n-1) \binom{n}{n-1} p^{n-2} (1-p)^{n-(n-1)} \\
& + \left\{ n \binom{n}{n} - \binom{n}{n-1} (n-(n-1)) \right\} \\
& \times p^{n-1} (1-p)^{n-n} \tag{9}
\end{aligned}$$

Since any expression of the form $(k+1) \binom{n}{k+1}$ is equivalent to $(n-k) \binom{n}{k}$, the coefficients of $p^i (1-p)^{n-i-1}$ for $i = k, k+1, \dots, n-1$ are zero.

That is,

$$\begin{aligned}
& (k+1) \binom{n}{k+1} - (n-k) \binom{n}{k} \\
& = (k+1) \frac{n!}{(n-k-1)!(k+1)!} \\
& \quad - (n-k) \frac{n!}{(n-k)!(k)!} \\
& = \frac{n!}{(n-k-1)!(k)!} - \frac{n!}{(n-k-1)!(k)!} \\
& = 0 \tag{10}
\end{aligned}$$

Therefore, the derivative of the reliability function with respect to p is given as

$$\frac{dR(k, n, p)}{dp} = k \binom{n}{k} p^{k-1} (1-p)^{n-k} \tag{11}$$

Note that the above derivative is positive meaning that the reliability function is increasing with respect to the parameter p .

Example 1 Evaluate the performance of a 2-out-of-5:G system with $p = 0.5$.

Solution:

$$\begin{aligned}
R(2, 5, 0.5) &= \sum_{i=2}^5 \binom{5}{i} 0.5^i (1-0.5)^{5-i} \\
&= P(X \geq 2) \\
&= 1 - P(X < 2) \\
&= 1 - P(X \leq 1) \\
&= 0.8125
\end{aligned}$$

Reliability Computations Assuming Exponential Distributions of Lifetimes

In the above section, the time to failure of a component was not considered in the calculation of the reliability of the system. Systems of any kind are either repairable or nonrepairable. In either case, the time until failure or repair must be considered. The time, T_i , until the failure of the i th component will now be included in the system reliability calculations. The time until failure of each of the components is a random variable. If the time until failure of all

4 k -out-of- n Systems

of the components is identically and independently distributed, the reliability function of the system may be expressed as in the first section with p replaced by $R(t)$, the reliability of each component. The reliability of the system, $R_s(t)$, may be expressed as

$$R_s(t) = \sum_{i=k}^n \binom{n}{i} R(t)^i (1 - R(t))^{n-i} \quad (12)$$

$R_s(t)$ may be thought of as the probability of at least k units working until time t . Similarly, $F_s(t) = 1 - R_s(t)$ is the probability of $k - 1$ or fewer units working until time t , where $F_s(t)$ is the cumulative distribution function of the system lifetime. $F_s(t)$ may be referred to as the *unreliability of the system*.

One of the main interests involving the system reliability is the mean time to failure of the system, denoted by $MTTF_s$. It can be shown, in general, that the expected value of a random variable defined on the interval $[0, \infty)$, is equivalent to the integral of the survival function of that random variable over the interval $[0, \infty)$. That is,

$$\begin{aligned} E(X) &= \int_x^\infty xf(x) dx = \int_x^\infty S(x) dx \\ &= \int_x^\infty (1 - F(x)) dx \end{aligned} \quad (13)$$

The mean time to failure of the system, $MTTF_s$, may be found by integrating the reliability of the system from zero to infinity, that is,

$$\int_0^\infty R_s(t) dt = MTTF_s \quad (14)$$

When the lifetimes of the components are i.i.d. and follow an exponential distribution, the $MTTF_s$ of a k -out-of- n :G system may be found explicitly. If the time until failure of each component is exponentially distributed with mean $1/\lambda$, then the reliability of each component is $R(t) = e^{-\lambda t}$ and the CDF is $F(t) = 1 - e^{-\lambda t}$. Since the time until failure for each component is independently and identically distributed, the probability that at least k components work may be expressed as

$$\begin{aligned} R_s(t) &= P(\text{exactly } k \text{ components work out of } n) \\ &\quad + P(\text{exactly } k + 1 \text{ components work out of } n) \\ &\quad + \cdots + P(\text{exactly } n \text{ components work out of } n) \end{aligned}$$

$$\begin{aligned} &= \binom{n}{k} (e^{-\lambda t})^k (1 - e^{-\lambda t})^{n-k} \\ &\quad + \binom{n}{k+1} (e^{-\lambda t})^{k+1} (1 - e^{-\lambda t})^{n-k-1} \\ &\quad + \cdots + \binom{n}{n} (e^{-\lambda t})^n (1 - e^{-\lambda t})^{n-n} \\ &= \sum_{i=k}^n \binom{n}{i} (e^{-\lambda t})^i (1 - e^{-\lambda t})^{n-i} \end{aligned} \quad (15)$$

Kuo and Zuo [1] show that if $k \geq 2$ the reliability of the system may be written recursively as

$$\begin{aligned} R_s(t; k, n) &= P(\text{at least } k \text{ components work out of } n) \\ &= P(\text{at least } k - 1 \text{ components work out of } n) \\ &\quad - P(\text{exactly } k - 1 \text{ components work out of } n) \\ &= R_s(t; k - 1, n) - \binom{n}{k-1} \\ &\quad \times (e^{-\lambda t})^{k-1} (1 - e^{-\lambda t})^{n-k+1} \end{aligned} \quad (16)$$

For $k \geq 2$, the mean time to failure of the system, $MTTF_s$, may be found by integrating both sides of equation (16) with respect to t as follows:

$$\begin{aligned} MTTF_s(k, n) &= MTTF_s(k - 1, n) - \binom{n}{k-1} \\ &\quad \times \int_0^\infty (e^{-\lambda t})^{k-1} (1 - e^{-\lambda t})^{n-k+1} dt \end{aligned} \quad (17)$$

The last term may be evaluated using integration by substitution and recognizing that the resulting integrand is the β **probability density function** divided by the constant $(\Gamma(\alpha)\Gamma(\beta))/\Gamma(\alpha + \beta)$, where $\alpha = n - k + 2$ and $\beta = k - 1$. That is, let $u = 1 - e^{-\lambda t}$, then $du = \lambda e^{-\lambda t} dt = \lambda(1 - u) dt$. Thus,

$$\begin{aligned} &\int_0^\infty \binom{n}{k-1} \frac{1}{\lambda} (e^{-\lambda t})^{k-1} (1 - e^{-\lambda t})^{n-k+1} dt \\ &= \binom{n}{k-1} \frac{1}{\lambda} \int_0^1 (1 - u)^{-1} (1 - u)^{k-1} (u)^{n-k+1} du \end{aligned}$$

$$\begin{aligned}
 &= \binom{n}{k-1} \frac{1}{\lambda} \frac{\Gamma(n-k+2) \Gamma(k-1)}{\Gamma(n-k+2+k-1)} \int_0^1 \\
 &\quad \frac{\Gamma(n-k+2+k-1)}{\Gamma(n-k+2)\Gamma(k-1)} (1-u)^{k-2} (u)^{n-k+1} du \\
 &= \binom{n}{k-1} \frac{1}{\lambda} \frac{\Gamma(n-k+2)\Gamma(k-1)}{\Gamma(n-k+2+k-1)} (1) \\
 &= \frac{n!}{(k-1)!(n-k+1)! \lambda} \frac{1}{\lambda} \frac{(n-k+1)!(k-2)!}{n!} \\
 &= \frac{(k-2)!}{\lambda(k-1)!} = \frac{1}{\lambda(k-1)} \quad (18)
 \end{aligned}$$

and

$$MTTF_s(k, n) = MTTF_s(k-1, n) - \frac{1}{\lambda(k-1)} \quad (19)$$

If $k = 1$, then

$$\begin{aligned}
 R_s(t; 1, n) &= P \left(\begin{array}{l} \text{at least 0 components} \\ \text{work out of } n \text{ components} \end{array} \right) \\
 &\quad - P \left(\begin{array}{l} \text{exactly 0 components} \\ \text{work out of } n \text{ components} \end{array} \right) \\
 &= 1 - \binom{n}{0} (e^{-\lambda t})^0 (1 - e^{-\lambda t})^{n-0} \\
 &= 1 - (1 - e^{-\lambda t})^n \quad (20)
 \end{aligned}$$

Expanding the last term, we see that the reliability of the system may be written as

$$\begin{aligned}
 R_s(t; 1, n) &= 1 - (1 - e^{-\lambda t})^n \\
 &= 1 - \left\{ \binom{n}{0} (-e^{-\lambda t})^n + \binom{n}{1} (-e^{-\lambda t})^{n-1} \right. \\
 &\quad + \binom{n}{2} (-e^{-\lambda t})^{n-2} + \cdots + \binom{n}{n-1} \\
 &\quad \times (-e^{-\lambda t})^1 + \left. \binom{n}{n} (-e^{-\lambda t})^0 \right\} \\
 &= - \left\{ \binom{n}{0} (-e^{-\lambda t})^n + \binom{n}{1} (-e^{-\lambda t})^{n-1} \right. \\
 &\quad + \binom{n}{2} (-e^{-\lambda t})^{n-2} \\
 &\quad + \cdots + \left. \binom{n}{n-1} (-e^{-\lambda t})^1 \right\} \quad (21)
 \end{aligned}$$

Integrating with respect to t from zero to infinity to calculate the mean time to failure, $MTTF_s$, gives

$$\begin{aligned}
 &MTTF_s(t; 1, n) \\
 &= \int_0^\infty R_s(t; 1, n) dt \\
 &= - \int_0^\infty \left\{ \binom{n}{0} (-e^{-\lambda t})^n + \binom{n}{1} (-e^{-\lambda t})^{n-1} \right. \\
 &\quad + \binom{n}{2} (-e^{-\lambda t})^{n-2} + \cdots + \binom{n}{n-2} (-e^{-\lambda t})^2 \\
 &\quad + \left. \binom{n}{n-1} (-e^{-\lambda t})^1 \right\} dt \\
 &= \frac{1}{\lambda} \left\{ \binom{n}{0} (-1)^n \frac{(e^{-\lambda t})^n}{n} \right. \\
 &\quad + \binom{n}{1} (-1)^{n-1} \frac{(e^{-\lambda t})^{n-1}}{n-1} + \binom{n}{2} (-1)^{n-2} \\
 &\quad \times \frac{(e^{-\lambda t})^{n-2}}{n-2} + \cdots + \binom{n}{n-2} (-1)^2 (e^{-\lambda t})^2 \\
 &\quad + \left. \binom{n}{n-1} (-1)^1 (e^{-\lambda t})^1 \right\} \Big|_0^\infty \\
 &= -\frac{1}{\lambda} \left\{ \binom{n}{0} (-1)^{n-0} \frac{1}{n} + \binom{n}{1} (-1)^{n-1} \frac{1}{(n-1)} \right. \\
 &\quad + \binom{n}{2} (-1)^{n-2} \frac{1}{(n-2)} \\
 &\quad + \cdots + \left. \binom{n}{n-2} (-1)^2 \frac{1}{2} + \binom{n}{n-1} (-1)^1 \right\} \\
 &= \frac{1}{\lambda} \left\{ \binom{n}{0} (-1)^{n-1} \frac{1}{n} + \binom{n}{1} (-1)^{n-1-1} \frac{1}{(n-1)} \right. \\
 &\quad + \binom{n}{2} (-1)^{n-2-1} \frac{1}{(n-2)} + \cdots + \\
 &\quad \times \left. \binom{n}{n-2} (-1)^{2-1} \frac{1}{2} + \binom{n}{n-1} (-1)^{1-1} \right\} \\
 &= \frac{1}{\lambda} \left\{ \binom{n}{n} (-1)^{n-1} \frac{1}{n} + \binom{n}{n-1} (-1)^{n-1-1} \right. \\
 &\quad \times \left. \frac{1}{(n-1)} + \binom{n}{n-2} (-1)^{n-2-1} \frac{1}{(n-2)} \right.
 \end{aligned}$$

$$\begin{aligned}
& + \cdots + \binom{n}{2} (-1)^{2-1} \frac{1}{2} + \binom{n}{1} (-1)^{1-1} \Big\} \\
& = \frac{1}{\lambda} \Big\{ \binom{n}{1} (-1)^{1-1} + \binom{n}{2} (-1)^{2-1} \frac{1}{2} \\
& \quad + \cdots + \binom{n}{n-2} (-1)^{n-2-1} \\
& \quad \times \frac{1}{(n-2)} + \binom{n}{n-1} (-1)^{n-1-1} \frac{1}{(n-1)} \\
& \quad + \binom{n}{n} (-1)^{n-1} \frac{1}{n} \Big\} \\
& = \frac{1}{\lambda} \sum_{i=1}^n \binom{n}{i} (-1)^{i-1} \frac{1}{i} \tag{22}
\end{aligned}$$

The sum $\sum_{i=1}^n \binom{n}{i} (-1)^{i-1} (1/i)$ in the above calculation is known as the *binomial harmonic identity* and is equivalent to $\sum_{i=1}^n (1/i)$, therefore, the mean time to failure of the system for $k = 1$ is

$$MTTF_s(1, n) = \frac{1}{\lambda} \sum_{i=1}^n \frac{1}{i} \tag{23}$$

Using the above result for $MTTF_s(1, n)$ and the recursive formula given for $MTTF_s(k, n)$, for $k \geq 2$, in equation (19), a closed-form expression for $MTTF_s(k, n)$ with a system of i.i.d. components with exponential distributions to lifetimes can easily be shown to be

$$MTTF_s(k, n) = \frac{1}{\lambda} \sum_{i=k}^n \frac{1}{i} \tag{24}$$

Example 2 Find the reliability and the $MTTF_s$ of a 2-out-of-4:G system in which the components have identical exponential lifetimes with mean 3.

Solution: The reliability of the system is given by

$$\begin{aligned}
R_s(t) &= \sum_{i=2}^4 \binom{4}{i} (e^{-(1/3)t})^i (1 - e^{-(1/3)t})^{n-i} \\
&= 6e^{-(2/3)t} (1 - e^{-(1/3)t})^2 \\
&\quad + 4e^{-t} (1 - e^{-(1/3)t}) + e^{-(4/3)t}
\end{aligned}$$

The $MTTF_s$ is

$$\begin{aligned}
MTTF_s &= 3 \sum_{i=2}^4 \frac{1}{i} \\
&= 3 \left(\frac{1}{2} + \frac{1}{3} + \frac{1}{4} \right) \\
&= \frac{13}{4}
\end{aligned}$$

Consecutive *k-out-of-n* Systems

Here we are talking about a *k-out-of-n* system that must have at least *k* consecutive components that fail before the system fails or at least *k* consecutive components that work for the system to continue to work. Only the circular and linear systems will be considered here. If the components are connected in a circular fashion, such as satellite communication networks, then the system is called a *circular k-out-of-n system*. Similarly, if the system is set up with components connected linearly, then the system is called a *linear k-out-of-n system*. The system will fail if at least *k* consecutive components of the *n* components fail. An example of this type of system is a communication relay system in which the signal is received and relayed at each station. A common shorthand method to refer to the *linear* and *circular* F and G systems are *Lin/Con/k/n:F*, *Lin/Con/k/n:G*, *Cir/Con/k/n:F*, and *Cir/Con/k/n:G*, which refer to linear consecutive *k-out-of-n:F* system, linear consecutive *k-out-of-n:G* system, circular consecutive *k-out-of-n:F* system, and circular consecutive *k-out-of-n:G* system, respectively. As in the previous sections, the components can only occupy one of the two states, either working or not working (failed).

Reliability Computations for Consecutive *k-out-of-n* System

In this section, the reliability computations will be calculated for systems with i.i.d. components. The linear consecutive *k-out-of-n:F* system will be considered first. There are several methods of computing the reliability of a *Lin/Con/k/n:F* system. The challenge in computing the reliability of this type of system is in counting the ways in which *j*, failed

components, can be arranged out of the n components so that there are at least k failed consecutive components in the system. First, let j represent the number of components that do not work so that $n - j$ represents the number of working components. If a combinatorial approach is used and the system is a *Lin/Con/2/n:F*, that is, $k = 2$, and the system works if at least every other component is working, it is easy to show that the reliability of the system is

$$\begin{aligned}
 R_{\text{linear}}(2, n) &= \binom{n+1}{0} (1-p)^0 p^{n+1} \\
 &\quad + \binom{n}{1} (1-p)^1 p^n \\
 &\quad + \cdots + \binom{n - \left\lfloor \frac{n+1}{2} \right\rfloor + 1}{\left\lfloor \frac{n+1}{2} \right\rfloor} \\
 &\quad \times (1-p)^{\left\lfloor \frac{n+1}{2} \right\rfloor} p^{n - \left\lfloor \frac{n+1}{2} \right\rfloor} \\
 &= \sum_{i=1}^{\lfloor (n+1)/2 \rfloor} \binom{n-i+1}{i} p^{n-i} (1-p)^i \\
 &= R_{\text{linear}}(2, n) = \sum_{i=1}^{\lfloor (n+1)/2 \rfloor} \binom{n-i+1}{i} p^{n-i} (1-p)^i \quad (25)
 \end{aligned}$$

where $p = P(\text{the component works})$ and $1 - p = P(\text{the component fails})$.

To calculate the reliability for a linear system for any k , $R_{\text{linear}}(k, n)$, it is necessary to find the number of ways to arrange the failed components so that there are no more than k consecutive failed components. A common symbol for this number is $N(j, k, n)$ and $R_{\text{linear}}(k, n)$ may be written as

$$R_{\text{linear}}(k, n) = \sum_{i=1}^n N(i, k, n) p^{n-i} (1-p)^i \quad (26)$$

Notice that some of the terms in equation (26) are zero because at some point as i approaches n there will be more than k consecutive failed components, meaning that the entire system would have already failed. There are several approaches to calculating an expression for $N(i, k, n)$. Bollinger [2]

developed a method to construct a table to calculate $N(i, k, n)$. Derman *et al.* [3] developed a recursive formula to calculate $N(i, k, n)$. To use equation (26) to find the reliability of the *Lin/Con/k/n:F* system, Satam [4] derived an expression for the maximum number of terms in the sum $R_{\text{linear}}(k, n)$ that are not zero, in other words, the maximum value of the index i . Let $\max$ represent the largest number of nonzero terms in the sum; then $\max$ is given by

$$\begin{aligned}
 \max &= \begin{cases} n - \frac{n+k}{k} + 1 & \text{if } n+1 \text{ is a multiple of } k \\ n - \left\lfloor \frac{n+1}{k} \right\rfloor & \text{if } n+1 \text{ is not a multiple of } k \end{cases} \quad (27)
 \end{aligned}$$

The reliability of the system may then be written as

$$R_{\text{linear}}(k, n) = \sum_{i=1}^{\max} N(i, k, n) p^{n-i} (1-p)^i \quad (28)$$

Two additional closed-form expressions of the reliability for the *Lin/Con/k/n:F* system are given by Goulden [5] and Hwang [6] as,

$$\begin{aligned}
 R_{\text{linear}}(k, n) &= \sum_{i=0}^{\lfloor n/(k+1) \rfloor} (-1)^i p^i (1-p)^{ki} \left[\binom{n-ki}{i} \right. \\
 &\quad \left. - (1-p)^k \binom{n-k(i+1)}{i} \right] \quad (29)
 \end{aligned}$$

and

$$\begin{aligned}
 R_{\text{linear}}(k, n) &= \sum_{i=0}^{\lfloor (n+1)/(k+1) \rfloor} (-1)^i p^{i-1} (1-p)^{ki} \\
 &\quad \times \left[\binom{n-ki+1}{i} - (1-p) \binom{n-ki}{i} \right] \quad (30)
 \end{aligned}$$

Example 3 Find the reliability of a *Lin/Con/k/n:F* system with $n = 15$, $k = 4$, and $p = 0.8$.

8 k -out-of- n Systems

Solution: Using the closed-form expression by Goulden, the reliability is calculated by the sum:

$$\begin{aligned}
 R_{\text{linear}}(3, 11) &= \sum_{i=0}^{\lfloor 15/5 \rfloor} (-1)^i (1 - 0.8)^{4i} (0.8)^i \left[\binom{15-3i}{i} \right. \\
 &\quad \left. - (1 - 0.8)^3 \binom{15-3(i+1)}{i} \right] \\
 &= (-1)^0 (0.2)^0 (0.8)^0 \left[\binom{15}{0} - (0.2)^3 \binom{12}{0} \right] \\
 &\quad + (-1)^1 (0.2)^4 (0.8)^1 \left[\binom{12}{1} - (0.2)^3 \binom{9}{1} \right] \\
 &\quad + (-1)^2 (0.2)^8 (0.8)^2 \left[\binom{9}{2} - (0.2)^3 \binom{6}{2} \right] \\
 &\quad + (-1)^3 (0.2)^{12} (0.8)^3 \left[\binom{6}{3} - (0.2)^3 \binom{3}{3} \right] \\
 &\approx 0.9768
 \end{aligned}$$

Circular Consecutive k -out-of- n :F System

The reliability of the $\text{Cir}/\text{Con}/k/n$:F system may be expressed in the same way as that of the $\text{Lin}/\text{Con}/k/n$:F system by

$$R_{\text{circular}}(k, n) = \sum_{i=0}^{\max} N_{\text{circular}}(i, k, n) p^{n-i} (1-p)^i \quad (31)$$

where, p is the probability that the component works, $(1-p)$ is the probability that the component fails, $N_{\text{circular}}(i, k, n)$ is the number of ways to obtain i failed components arranged in a circle such that no more than k failed components are consecutive and $\max$ is the maximum number of failed components that can occur until the system fails. The value of $\max$ may be calculated by

$$\max = \begin{cases} n - \frac{n}{k} & \text{if } n \text{ is a multiple of } k \\ n - \left\lfloor \frac{n}{k} \right\rfloor - 1 & \text{if } n \text{ is not a multiple of } k \end{cases} \quad (32)$$

Other equations to evaluate the reliability of a $\text{Cir}/\text{Con}/k/n$:F system are given respectively by

Goulden [5] and Lambiris and Papastavridis [7] as

$$\begin{aligned}
 R_{\text{circular}}(k, n) &= 1 - q^n + n \sum_{i=1}^{\lfloor n/(k+1) \rfloor} \frac{(-1)^i}{i} p^i q^{ki} \\
 &\quad \times \binom{n-ik-1}{i-1}, \quad n \geq k \quad (33)
 \end{aligned}$$

$$\begin{aligned}
 R_{\text{circular}}(k, n) &= R_{\text{circular}}(k, n-1) - (pq^k) \\
 &\quad \times R_{\text{circular}}(k, n-k-1), \quad n \geq 2k+1 \quad (34)
 \end{aligned}$$

Equation (34) is the most efficient way to evaluate the reliability of the $\text{Cir}/\text{Con}/k/n$:F system with a computational complexity of $O(n)$.

The $\text{Cir}/\text{Con}/k/n$:F system may be treated as a special case of the reliability function of the $\text{Lin}/\text{Con}/k/n$:F system. Derman *et al.* [3] developed the following recursive relationship for $R_{\text{circular}}(k, n)$.

$$\begin{aligned}
 R_{\text{circular}}(k, n) &= \sum_{i=0}^{k-1} (i+1) p^2 q^i R_{\text{linear}}(k, n-i-2) \\
 &= \sum_{i=0}^{k-1} (i+1) P(N+N'=i) \\
 &\quad P(\text{at least } k \text{ consecutive components} \\
 &\quad \text{work out of } n-i-2) \quad (35)
 \end{aligned}$$

N and N' are computed as follows. Choose a component in the circular system. Arrange the components linearly with the chosen component as the first component in a linear arrangement. Let N be the number of failed components until the first working component is found starting from the first component. Next, arrange the components linearly, but now let the chosen component be the last component and let N' be the number of failed components until the first working component is found starting the count from the last component. Notice, $P(N=i) = P(N'=i) = p(1-p)^i$ for $i = 1, 2, \dots, n-1$ and if $i \leq n-2$,

then

$$\begin{aligned}
 P(N + N' = i) &= \sum_{j=0}^i P(N = j)P(N = i - j) \\
 &= \sum_{j=0}^i p(1 - p)^j p(1 - p)^{i-j} \\
 &= p^2 q^i \quad \text{for } i = 0, 1, 2, \dots, n - 2
 \end{aligned} \tag{36}$$

Example 4 Find the reliability of a *Cir/Con/k/n:F* system with $n = 15$, $k = 4$, and $p = 0.8$.

Solution: Using the expression (15) by Goulden the reliability is calculated by

$$\begin{aligned}
 R_{\text{circular}}(k, n) \\
 = 1 - q^n + n \sum_{i=1}^{\lfloor n/(k+1) \rfloor} \frac{(-1)^i}{i} p^i q^{ki} \binom{n - ik - 1}{i - 1}
 \end{aligned} \tag{37}$$

$$\begin{aligned}
 R_{\text{circular}}(4, 15) \\
 = 1 - 0.2^{15} + 15 \sum_{i=1}^3 \frac{(-1)^i}{i} (0.8)^i (0.2)^{4i} \\
 \times \binom{15 - 4i - 1}{i - 1}
 \end{aligned}$$

$$\begin{aligned}
 &= 1 - 0.2^{15} + 15 \left\{ - (0.8)^1 (0.2)^4 \binom{10}{0} \right. \\
 &\quad \left. + \frac{1}{2} (0.8)^2 (0.2)^8 \binom{6}{1} - \frac{1}{3} (0.8)^3 (0.2)^{12} \binom{2}{2} \right\} \\
 &= 0.9809
 \end{aligned} \tag{38}$$

DEBORAH K. SHEPHERD

Path Sets and Cut Sets in System Reliability Modeling

Background and Preliminaries

Graphs

Definitions. A *graph* is an ordered pair of sets $(\mathcal{N}, \mathcal{L}) = \mathcal{G}$ with $\mathcal{L} \subset \mathcal{N} \times \mathcal{N}$. $\mathcal{N}$ is called the *set of nodes* of the graph and $\mathcal{L}$ is called the *set of links* of the graph. Typically, a graph is identified with a drawing in which the nodes are represented as points in the plane and the links are represented as lines drawn to join two nodes. In other terminology in common use, the nodes may be called *vertices* and the links may be called *arcs* or *edges*.

A *labeled graph* is a graph in which the nodes and/or links have names. That is, there is a one-to-one correspondence between the nodes of the graph and a set of $|\mathcal{N}|$ objects (the node labels) and/or between the links of the graph and a set of $|\mathcal{L}|$ objects (the link labels).

A *directed graph* is a graph in which each link is assigned an orientation or direction. In a directed graph, the links (i, j) and (j, i) are different, whereas in an ordinary (undirected) graph, they are identical. The concept of “a link from i to j ” makes sense in a directed graph; in an undirected graph it would be proper to say, rather, “a link between i and j ”.

Examples. The cities in a state, together with the roads joining them, may be described as a graph. In this example, the cities form the nodes of the graph and the roads joining them form the links. A natural labeling of the nodes and links exists. A natural gas pipeline may be modeled as a graph with the terminals and transfer stations as the nodes and the pipes as the links. Graphs find application in the social sciences also. A graph may be constructed from a set of individuals (who form the nodes) in which two individuals are joined by a link if they are known to each other. Indeed, any binary reflexive relation between discrete entities gives rise to a graph in which the entities are the nodes and a link joins two nodes if the relation holds for those two nodes. If the relation is not reflexive, then the result is a

directed graph. If there is a notion of “strength” of the relationship and we wish to incorporate this notion into the model, a more appropriate approach is to model the graph as a capacitated network; *see* the section titled “Paths, Cuts, and Demand Satisfaction in Capacitated Networks”.

References. Other useful graph concepts, such as degree, are not covered in this article because they are not relevant to the reliability modeling application. For a review of the basic facts of graph theory, see [1–3].

Paths and Connectedness

Definitions. Two nodes i and j are *adjacent* if $(i, j) \in \mathcal{L}$. The *adjacency matrix* of $\mathcal{G}$ is an $|\mathcal{N}| \times |\mathcal{N}|$ matrix whose ij entry is one if $(i, j) \in \mathcal{L}$ and is zero otherwise. In other terminology in common use, the adjacency matrix may be called the *incidence matrix*. A *path* in a graph is a sequence of alternating adjacent nodes and the links joining them, beginning and ending with a node. Two nodes i and j are said to be *connected* if there is a path having i as its initial node and j as its terminal node. That is, the path takes the form $\{i, (i, v_1), v_1, (v_1, v_2), \dots, v_k, (v_k, j), j\}$ for some $v_1, \dots, v_k \in \mathcal{N}$ and $(i, v_1), (v_1, v_2), \dots, (v_k, j) \in \mathcal{L}$. There is no loss in abbreviating this to $\{(i, v_1), (v_1, v_2), \dots, (v_k, j)\}$. When it is necessary or desirable to explicitly indicate the nodes being connected, the path will be called an (i, j) *path*. Clearly, adjacent nodes are connected but connected nodes need not be adjacent. If the graph is directed, the links in the path must be considered with the proper orientation.

A *cut* for two given nodes is a set of nodes and/or links whose removal from the graph disconnects the two nodes. When it is necessary or desirable to explicitly indicate the nodes being disconnected, the cut will be called an (i, j) *cut*.

A path connecting two given nodes is called *minimal* if it contains no proper subset that is also a path connecting the same two nodes. A cut for two given nodes is called *minimal* if it contains no proper subset that is also a cut disconnecting those nodes.

Examples. The Washington, DC, Metro subway system <http://www.wmata.com/metro/rail/systemmap.cfm> may be modeled as a graph with the stations as

the nodes. In this graph, the Pentagon and College Park – University of Maryland are connected but not adjacent. DuPont Circle and Farragut North are both connected and adjacent. The Manhattan (NY) city streets may be modeled as a graph with the intersections as the nodes. For vehicle traffic, this graph is directed because many streets in Manhattan are one-way. For pedestrian traffic, the graph need not be directed.

Random Graphs

Definitions. A *random graph* is a graph in which a stochastic indicator variable is attached to each node and link. When the variable is zero, it indicates that, that node or link is not present in the graph. When it is one, it indicates that, that node or link is present in the graph. Each choice of values for these indicator variables, by whatever random mechanism is at play, produces a different graph (the choice is not completely unrestricted; if the indicator of a node is zero, the indicators of all the links emanating from that node must be zero also). The adjacency matrix of a random graph is a random matrix.

In a reliability engineering application, the indicator variable for a link or node describes the functioning or nonfunctioning of the link or node. The usual convention is that the indicator variable is one when the link or node functions and zero if it does not function. There is no fundamental reason why the opposite assignment could not be used, and it is sometimes seen.

References. For purposes of the reliability modeling described in this article, this definition is as much of the subject of random graphs as we will use. Additional material on random graphs may be found in [4] and [5].

Paths, Cuts, and System Reliability Modeling

Introduction: Structure Functions and Reliability Block Diagrams

For the purposes of this article, reliability is considered an all-or-nothing condition: either a unit or system functions properly and completely at a stated time, or it does not function at all at that time. Thus,

we may imagine the functioning-or-failed condition of a unit or system as a zero-one, or indicator, random variable that, in the general case, will be allowed to depend on time. The system *structure function* is a Boolean function that maps $\{0, 1\}^c$ into $\{0, 1\}$, where the number of components in the system is c . The structure function is the indicator variable of the system functioning when the arguments in the structure function are replaced by the indicator variables of the components' functioning. Let X_k indicate the functioning of component k and $x_k \in \{0, 1\} (k = 1, \dots, c)$. The system structure function is $\varphi(x_1, \dots, x_c)$ and the system reliability is $P\{\varphi(X_1, \dots, X_c) = 1\}$. For example, the structure function for a series system of c components is $\varphi(x_1, \dots, x_c) = x_1 x_2 \cdots x_c$.

A structure function is called *coherent* if it is nondecreasing in each variable separately and each component is relevant (that is, the state of the system depends on the states of all the components in the structure function).

The system reliability block diagram is a labeled random graph whose links represent the components or subsystems whose reliability description is known or provided (for analysis of a system reliability block diagram, it is sufficient to allow the nodes to be perfectly reliable). The system reliability block diagram expresses the reliability logic of a system in the sense that it shows how the system fails when constituent components and subsystems fail. It is a pictorial representation of the system structure function. Two special nodes are called out: a source or origin node and a terminal or destination node. The system functions if and only if in the random graph there is a path connecting the source node to the terminal node.

In many cases, the system reliability block diagram is a *series-parallel* structure. In such cases, the probability that the system functions is easily concluded from nesting of the standard formulas for the reliability of series systems and parallel systems (see **Parallel, Series, and Series-Parallel Systems**). Other structures, such as the *k-out-of-n* hot standby and *k-out-of-n* cold standby structures, are also amenable to similar probabilistic analysis. Some other structures, such as the bridge structure shown in Figure 1, lend themselves less readily to this type of analysis. In such cases, it may be convenient to use the path set or the cut set methods that are the subject of this article.

Figure 1 Bridge network

Path Sets and Cut Sets

Given two nodes in a graph, the *path set* for those two nodes is the union of all paths connecting those two nodes. In other terminology in common use, a path set may be called a *tie set*. The *cut set* for those two nodes is the union of all cuts for those two nodes. The *minimal path set* is the union of all minimal paths. The *minimal cut set* is the union of all minimal cuts.

Some authors use the phrases “path set” for what we call a *path* and “cut set” for what we call a *cut*. This makes the naming of the path set or cut set (as defined here) less natural and we avoid that difficulty by using this scheme.

The key concept is that the system functions if and only if there is at least one minimal path whose components are all in a functioning condition. Similarly, the system does not function if and only if there is at least one minimal cut whose components are all in a failed (nonfunctioning) condition. The random graph model provides a framework for computing probabilities of system functioning and failure (nonfunctioning) based on these concepts.

Examples

Consider the reliability block diagram depicted in Figure 2. The small circles represent the nodes of this random graph and these are assumed not to fail. The links representing subsystems that can fail individually in this system have been labeled for convenience by the letters A, B, C, D, and E. The two unlabeled links in the center of the diagram are not associated with any subsystems and are assumed not to fail. Note that, like the bridge structure of Figure 1, this is not a series-parallel graph. In this model, the

Figure 2 Example of a reliability block diagram

system functions if the node s at the left-hand edge of the diagram and the node t at the right-hand edge of the diagram are connected. This representation indicates that the system functions if any one of the sets $\{A, B\}$, $\{D, E\}$, $\{C, B\}$, or $\{C, E\}$ of units consists entirely of functioning units. Each of these is an (s, t) path. The union of these five paths constitutes the path set for the node pair (s, t) . Note that all these paths are minimal, and these are the only minimal paths, so the path set $\{A, B\} \cup \{D, E\} \cup \{C, B\} \cup \{C, E\}$ is the minimal path set.

Similarly, the system fails to function if any of the sets $\{B, E\}$, $\{A, C, D\}$, $\{C, B, D\}$, or $\{C, A, E\}$ consists entirely of nonfunctioning, or failed, units. Any one of these is a cut for (s, t) , or an (s, t) cut. There are other (s, t) cuts in this graph, such as $\{A, B, E\}$, but the four cuts enumerated above are the only minimal cuts. The minimal cut set for (s, t) is their union $\{B, E\} \cup \{A, C, D\} \cup \{C, B, D\} \cup \{C, A, E\}$.

System Reliability Modeling and Computation Using Path Sets and Cut Sets

Path Set Method

Because the path set contains all paths connecting s to t , for the system to function it suffices that at least one path be made up entirely of functioning units. Therefore, the probability that the system functions is given by the probability of the path set in the labeled random graph representing the system reliability block diagram. However, only minimal paths need be considered because if a path is not a minimal path,

4 Path Sets and Cut Sets in System Reliability Modeling

then it has a proper subset that is still a path and is a member of the minimal path set. In other words, the union of all (s, t) paths is equal to the union of all (s, t) minimal paths. Consequently, we have the following result:

Proposition 1. The probability that the system functions is given by the probability of the system's minimal path set.

Example. Consider again the system shown in Figure 2. Letting $p_A = P\{A = 1\}$ (where we have abused notation slightly by identifying the indicator random variable's letter with the unit's label) and similarly for B, C, D, and E, the probability that the system functions is given by

$$P(\{A = 1, B = 1\} \cup \{D = 1, E = 1\} \cup \{C = 1, B = 1\} \cup \{C = 1, E = 1\}) \quad (1)$$

This equation shows the strength and weaknesses of the path set method. Its strength is that it is completely straightforward and mechanical to write the expression for the probability that the system functions once the path sets are known. Its weaknesses are that (a) enumerating the paths connecting s and t is tedious for all but the simplest of graphs and (b) the expression that results is the probability of a large union of events that are not, in general, disjoint. However, these weaknesses pertain mainly to manual execution; the algorithmic nature of the procedure means that software for path set reliability analysis is within reach, and indeed has been available for some time [8].

General Representation of System Reliability via the Minimal Path Set. As usual, let $\mathbf{x} = (x_1, \dots, x_c)$ denote the vector of indicators of the functioning of the c components of the system. Enumerate the minimal paths of the system; suppose there are m of them called $\pi_1, \dots, \pi_m$. The structure function for the series system represented by the minimal path π_k is

$$\varphi_k(\mathbf{x}) = \prod_{i \in \pi_k} x_i \quad (2)$$

for $k = 1, \dots, m$. The system functions if and only if at least one of the minimal paths consists entirely of functioning units, so it follows that the structure function for the system may be written as

$$\varphi(\mathbf{x}) = 1 - \prod_{k=1}^m [1 - \varphi_k(\mathbf{x})] = 1 - \prod_{k=1}^m [1 - \prod_{i \in \pi_k} x_i] \quad (3)$$

This equation shows how the system structure function may be represented in terms of the structure functions of the system's minimal paths.

Cut Set Method

Because the cut set contains all (s, t) cuts, for the system to fail it suffices that at least one cut be made up entirely of nonfunctioning units. However, only minimal cuts need be considered because if a cut is not a minimal cut, then it has a proper subset that is still a cut and is a member of the minimal cut set. In other words, the union of all (s, t) cuts is equal to the union of all (s, t) minimal cuts. Therefore, the probability that the system fails to function is given by the probability of the minimal cut set in the labeled random graph representing the system reliability block diagram. Consequently, we have the following result:

Proposition 2. The probability that the system fails is given by the probability of the system's minimal cut set.

Example. Consider again the system shown in Figure 2. The probability that the system fails to function is given by

$$P(\{B = 0, E = 0\} \cup \{A = 0, C = 0, D = 0\} \cup \{C = 0, B = 0, D = 0\} \cup \{C = 0, A = 0, E = 0\}) \quad (4)$$

Again, equation (4) represents the probability of a union of events that are not, in general, disjoint so manual computation can become cumbersome. An algorithm for system reliability evaluation using cut sets may be found in [3].

General Representation of System Reliability via the Minimal Cut Set. Enumerate the minimal cuts of the system; suppose there are n of them called $\chi_1, \dots, \chi_n$. The structure function for the series system represented by the minimal cut χ_k is

$$\varphi_k(\mathbf{x}) = 1 - \prod_{i \in \chi_k} (1 - x_i) \quad (5)$$

for $k = 1, \dots, n$. The system fails if and only if at least one of the minimal cuts consists entirely of nonfunctioning units, so it follows that the structure function for the system may be written as

$$\varphi(\mathbf{x}) = \prod_{k=1}^n \varphi_k(\mathbf{x}) = \prod_{k=1}^n \left[1 - \prod_{i \in \chi_k} (1 - x_i) \right] \quad (6)$$

This equation shows how the system structure function may be represented in terms of the structure functions of the system's minimal cuts.

References. Additional information on the use of path sets and cuts sets for system reliability modeling and computation may be found in [6] and [9].

Bounds

The minimal path set and minimal cut set representations for the system reliability lend themselves readily to the development for bounds on the system reliability. The first such bounds were developed by Esary and Proschan [3]. Letting C (resp., W) denote the minimal cut (resp., path) set for the system, i.e., for the nodes (s, t) , Esary and Proschan's lower bound for the system reliability is

$$\prod_{c \in C} \left(1 - \prod_{i \in c} P\{X_i = 0\} \right) \quad (7)$$

and their upper bound is

$$1 - \prod_{w \in W} \left(1 - \prod_{i \in w} P\{X_i = 1\} \right) \quad (8)$$

The lower bound gives good approximations for highly reliable systems, while the upper bound works better for systems whose components have low reliability. Numerous improvements have been developed; we refer especially to [10] and [11] for later developments.

Paths, Cuts, and Demand Satisfaction in Capacitated Networks

A *network* is a directed graph containing two distinguished subsets $\mathcal{O}$ and $\mathcal{D}$ of $\mathcal{N}$, the sets of origin nodes and destination nodes, respectively. A network is *capacitated* if there is an assignment of nonnegative real numbers to each link and node that represents the *capacity* of that link or node. Origin nodes and destination nodes are called so because the network is required to transport given quantities

of some commodity, discrete (package shipments, telecom/datacom packets) or continuum (oil, gas), tangible (postal letters) or intangible (sensor readings) from the origin node(s) to the destination node(s). The matrix of required quantities is the *exogenous demand*. In other terminology in common use, the origin nodes may be called *sources* and the destination nodes may be called *sinks*.

A *flow* in a network is a map that assigns to each link a nonnegative real number that represents the quantity of the commodity present on that link; see [10]. Sometimes, we speak of the flow on a link (or at a node) to mean the real number in the flow that is attached to that link or node. In a capacitated network, this is required to be no greater than the capacity of the link or node. Determining the flow from the origin-to-destination demands usually requires solution of some optimization problem (such as minimum cost) and is beyond the scope of this article. Nonetheless, in seeking the probability that the demand is satisfied, that is, that the required number of units is transported to the destination nodes, the concepts of path and cut may be generalized to yield useful methods.

The flow into a node is equal to the sum of the flows on the links terminating on that node. Similarly, the flow out of a node is equal to the sum of the flows on the links originating from that node. To say that a demand is satisfied is to say that the flows into the destination nodes are all at least as large as the amount of the commodity required to be delivered to the destinations (in the exogenous demand). Demand satisfaction is a generalization of connectivity. Connectivity is necessary for demand satisfaction: if two nodes are not connected by any paths, then the flow into the terminal node will be zero. Ramirez-Marquez *et al.* [12] developed a generalization of the cut set method described above that is appropriate for demand satisfaction in capacitated networks.

MICHAEL TORTORELLA

Component Reliability Importance

Introduction

Consider an n -component coherent system having components whose reliabilities can be expressed in the vector $\mathbf{p} = (p_1, p_2, \dots, p_n)$. The system reliability is then a function of the component reliabilities, so we write

$$r(\mathbf{p}) = P(\text{system functions if components have reliabilities } \mathbf{p}) \quad (1)$$

The *reliability importance* $I(k)$ of component k is defined to be the rate of change in system reliability with respect to the reliability p_k of component k ; in other words

$$I(k) = \frac{\partial r(\mathbf{p})}{\partial p_k} \quad k = 1, 2, \dots, n \quad (2)$$

An alternative formula for the reliability importance of component k can be obtained from decomposition:

$$\begin{aligned} r(\mathbf{p}) &= P(\text{system works}) \\ &= P(\text{(component } k \text{ works and system works)} \\ &\quad \text{or (component } k \text{ fails and system works)}) \\ &= P(\text{component } k \text{ works})P(\text{system works} \mid \\ &\quad \text{component } k \text{ works}) \\ &\quad + P(\text{component } k \text{ fails})P(\text{system works} \mid \\ &\quad \text{component } k \text{ fails}) \end{aligned} \quad (3)$$

If we let $(1_k, \mathbf{p}) = (p_1, p_2, \dots, p_{k-1}, 1, p_{k+1}, \dots, p_n)$ denote the vector $\mathbf{p}$ with 1 in place of p_k , and similarly $(0_k, \mathbf{p}) = (p_1, p_2, \dots, p_{k-1}, 0, p_{k+1}, \dots, p_n)$, then we can write

$$r(\mathbf{p}) = p_k r(1_k, \mathbf{p}) + (1 - p_k) r(0_k, \mathbf{p}) \quad (4)$$

Differentiating both sides with respect to p_k gives

$$I(k) = \frac{\partial r(\mathbf{p})}{\partial p_k} = r(1_k, \mathbf{p}) - r(0_k, \mathbf{p}) \quad (5)$$

This gives an alternative interpretation of the reliability importance: the difference in the reliabilities if component k does and does not work.

Reliability importance is described in detail in Barlow and Proschan [1].

Examples

Series System

For a **series system** with component reliabilities $\mathbf{p} = (p_1, p_2, \dots, p_n)$, the reliability function is

$$r(\mathbf{p}) = \prod_{i=1}^n p_i = p_1 p_2 \cdots p_k \cdots p_n \quad (6)$$

so that

$$\begin{aligned} I(k) &= \frac{\partial r(\mathbf{p})}{\partial p_k} = \frac{\partial}{\partial p_k} [(p_1 p_2 \cdots p_{k-1} p_{k+1} \cdots p_n) p_k] \\ &= (p_1 p_2 \cdots p_{k-1} p_{k+1} \cdots p_n) \\ &= \frac{p_1 p_2 \cdots p_{k-1} p_{k+1} \cdots p_n}{p_k} \\ &= \frac{r(\mathbf{p})}{p_k} \end{aligned} \quad (7)$$

Thus, the reliability importance of component k is the product of the reliabilities of all components except component k , or equivalently, it is equal to the system reliability divided by the component reliability p_k . Thus, the least reliable component is the one with the greatest reliability importance. This makes intuitive sense: the system reliability is improved the most when the least reliable component is improved.

For illustration, suppose that the components have reliabilities

$$p_1 = 0.9 \quad (8)$$

$$p_2 = 0.99 \quad (9)$$

$$p_3 = 0.95 \quad (10)$$

The reliability importance for the three components are

$$I(1) = p_2 p_3 = 0.99 \times 0.95 = 0.9405 \quad (11)$$

$$I(2) = p_1 p_3 = 0.9 \times 0.95 = 0.855 \quad (12)$$

$$I(3) = p_1 p_2 = 0.9 \times 0.99 = 0.891 \quad (13)$$

For a series system, the structure is symmetric in the components, meaning that interchanging components leads to the same system structure, so if the

2 Component Reliability Importance

component reliabilities are all equal, this would imply that all components have equal importance. This is clearly true since

$$I(k) = \frac{r(\mathbf{p})}{p_k} = \frac{p^n}{p} = p^{n-1} \quad (14)$$

for all k .

Parallel System

For a **parallel system**, the reliability function is

$$r(\mathbf{p}) = 1 - \prod_{i=1}^k (1 - p_i) = 1 - (1 - p_1) \times (1 - p_2) \cdots (1 - p_k) \cdots (1 - p_n) \quad (15)$$

so the reliability importance of the k th component is

$$\begin{aligned} \frac{\partial r(\mathbf{p})}{\partial p_k} &= \frac{\partial}{\partial p_k} [1 - (1 - p_1) \times (1 - p_2) \cdots (1 - p_k) \cdots (1 - p_n)] \\ &= -(1 - p_1)(1 - p_2) \cdots (1 - p_{k-1}) \\ &\quad \times (1 - p_{k+1}) \cdots (1 - p_n)(-1) \\ &= (1 - p_1)(1 - p_2) \cdots (1 - p_{k-1}) \\ &\quad \times (1 - p_{k+1}) \cdots (1 - p_n) \\ &= \frac{(1 - p_1)(1 - p_2) \cdots (1 - p_n)}{1 - p_k} \\ &= \frac{1 - r(\mathbf{p})}{1 - p_k} \end{aligned} \quad (16)$$

Thus, since the numerator is a constant, independent of k , the component with the highest reliability is the one with the greatest reliability importance. In a parallel system, the system reliability is improved the most when the most reliable component is improved.

If the component reliabilities are

$$p_1 = 0.8 \quad (17)$$

$$p_2 = 0.9 \quad (18)$$

$$p_3 = 0.95 \quad (19)$$

$$p_4 = 0.99 \quad (20)$$

then the system reliability is

$$r(\mathbf{p}) = 0.99999 \quad (21)$$

and the reliability importances are

$$I(1) = \frac{1 - 0.99999}{1 - 0.8} = 0.00005 \quad (22)$$

$$I(2) = \frac{1 - 0.99999}{1 - 0.9} = 0.0001 \quad (23)$$

$$I(3) = \frac{1 - 0.99999}{1 - 0.95} = 0.0002 \quad (24)$$

$$I(4) = \frac{1 - 0.99999}{1 - 0.99} = 0.001 \quad (25)$$

Series-Parallel Systems

Consider the **series-parallel system** shown in Figure 1.

For this system, the reliability function is

$$r(\mathbf{p}) = [1 - (1 - p_1)(1 - p_2)][1 - (1 - p_3)(1 - p_4)] \times [1 - (1 - p_5)(1 - p_6)] \quad (26)$$

The reliability importances are

$$I(1) = \frac{\partial r(\mathbf{p})}{\partial p_1} = (1 - p_2) \times [1 - (1 - p_3)(1 - p_4)] \times [1 - (1 - p_5)(1 - p_6)] \quad (27)$$

$$I(2) = \frac{\partial r(\mathbf{p})}{\partial p_2} = (1 - p_1) \times [1 - (1 - p_3)(1 - p_4)] \times [1 - (1 - p_5)(1 - p_6)] \quad (28)$$

$$I(3) = \frac{\partial r(\mathbf{p})}{\partial p_3} = (1 - p_4) [1 - (1 - p_1)(1 - p_2)] \times [1 - (1 - p_5)(1 - p_6)] \quad (29)$$

$$I(4) = \frac{\partial r(\mathbf{p})}{\partial p_4} = (1 - p_3) [1 - (1 - p_1)(1 - p_2)] \times [1 - (1 - p_5)(1 - p_6)] \quad (30)$$

$$I(5) = \frac{\partial r(\mathbf{p})}{\partial p_5} = (1 - p_6) [1 - (1 - p_1)(1 - p_2)] \times [1 - (1 - p_3)(1 - p_4)] \quad (31)$$

Figure 1 Series-parallel system with six components

$$I(6) = \frac{\partial r(\mathbf{p})}{\partial p_6} = (1 - p_5) [1 - (1 - p_1)(1 - p_2)] \times [1 - (1 - p_3)(1 - p_4)] \quad (32)$$

In the special case where $p_1 = p_2 = 0.9$, $p_3 = p_4 = 0.95$, and $p_5 = p_6 = 0.99$, the component importances are

$$I(1) = I(2) = (1 - p_1) [1 - (1 - p_3)^2] \times [1 - (1 - p_5)^2] = 0.09974 \quad (33)$$

$$I(3) = I(4) = (1 - p_3) [1 - (1 - p_1)^2] \times [1 - (1 - p_5)^2] = 0.0494951 \quad (34)$$

$$I(5) = I(6) = (1 - p_5) [1 - (1 - p_1)^2] \times [1 - (1 - p_3)^2] = 0.00987525 \quad (35)$$

Structural Importance

The structural importance of a component is related to the structure of the system, but does not depend on the system reliabilities. Consider for instance the system whose block diagram is shown in Figure 2. It would seem that component 1 is most important, because the system does not function without it.

In general, we let $\mathbf{x} = (x_1, x_2, \dots, x_n)$ be the vector of zeros and ones representing the state of the components, where $x_i = 1$ if component i is working and 0 if it is not working. The structure function (for a given system) is

$$\phi(\mathbf{x}) = \begin{cases} 1, & \text{if the system works for the state vector } \mathbf{x} \\ 0, & \text{if the system fails for the state vector } \mathbf{x} \end{cases} \quad (36)$$

Then let $(1_k, \mathbf{x}) = (x_1, x_2, \dots, x_{k-1}, 1, x_{k+1}, \dots, x_n)$ and $(0_k, \mathbf{x}) = (x_1, x_2, \dots, x_{k-1}, 0, x_{k+1}, \dots, x_n)$. If for a given vector $\mathbf{x}$ and component k , the system works if $x_k = 1$ and fails if $x_k = 0$, that is,

$$\phi(1_k, \mathbf{x}) - \phi(0_k, \mathbf{x}) = 1 \quad (37)$$

then component k would seem important. If, on the other hand,

$$\phi(1_k, \mathbf{x}) - \phi(0_k, \mathbf{x}) = 0 \quad (38)$$

Figure 2 A four-component system

Table 1 Computation of $I_\phi(1)$

$\mathbf{x}$	$\phi(1_1, \mathbf{x})$	$\phi(0_1, \mathbf{x})$	$\phi(1_1, \mathbf{x}) - \phi(0_1, \mathbf{x})$
(*, 0, 0, 0)	0	0	0
(*, 0, 0, 1)	0	0	0
(*, 0, 1, 0)	0	0	0
(*, 0, 1, 1)	1	0	1
(*, 1, 0, 0)	1	0	1
(*, 1, 0, 1)	1	0	1
(*, 1, 1, 0)	1	0	1
(*, 1, 1, 1)	1	0	1

then system works (fails) whether component k works (fails), suggesting that component k is not so important.

The *structural reliability importance* of component k is obtained by averaging the differences $\phi(1_k, \mathbf{x}) - \phi(0_k, \mathbf{x})$ over all 2^{n-1} possible state vectors $\mathbf{x}$ (without component k). Specifically,

$$I_\phi(k) = \frac{1}{2^{n-1}} \sum_{\{\mathbf{x}: x_k=1\}} [\phi(1_k, \mathbf{x}) - \phi(0_k, \mathbf{x})] \quad (39)$$

For illustration, consider the four component system in Figure 2. Table 1 shows all eight state vectors (excluding the first component) and the values $\phi(1_k, \mathbf{x})$ and $\phi(0_k, \mathbf{x})$. From this table, we can compute the structural reliability importance for component 1:

$$\begin{aligned} I_\phi(1) &= \frac{1}{2^{4-1}} \sum_{\{\mathbf{x}: x_1=1\}} [\phi(1_1, \mathbf{x}) - \phi(0_1, \mathbf{x})] \\ &= \frac{1}{8} [0 + 0 + 0 + 1 + 1 + 1 + 1 + 1] = \frac{5}{8} \end{aligned} \quad (40)$$

The corresponding tables for components 2 and 3 are shown in Tables 2 and 3. From this we can compute the structural importance of component 2 and 3 (by symmetry, components 3 and 4 have the same structural reliability importance):

$$I_\phi(2) = \frac{1}{8} [0 + 0 + 0 + 0 + 1 + 1 + 1 + 0] = \frac{3}{8}$$

4 Component Reliability Importance

Table 2 Computation of $I\phi(2)$

$\mathbf{x}$	$\phi(1_2, \mathbf{x})$	$\phi(0_2, \mathbf{x})$	$\phi(1_2, \mathbf{x}) - \phi(0_2, \mathbf{x})$
(0, *, 0, 0)	0	0	0
(0, *, 0, 1)	0	0	0
(0, *, 1, 0)	0	0	0
(0, *, 1, 1)	0	0	0
(1, *, 0, 0)	1	0	1
(1, *, 0, 1)	1	0	1
(1, *, 1, 0)	1	0	1
(1, *, 1, 1)	1	1	0

Table 3 Computation of $I\phi(3) = I\phi(4)$

$\mathbf{x}$	$\phi(1_3, \mathbf{x})$	$\phi(0_3, \mathbf{x})$	$\phi(1_3, \mathbf{x}) - \phi(0_3, \mathbf{x})$
(0, 0, *, 0)	0	0	0
(0, 0, *, 1)	0	0	0
(0, 1, *, 0)	0	0	0
(0, 1, *, 1)	0	0	0
(1, 0, *, 0)	0	0	0
(1, 0, *, 1)	1	0	1
(1, 1, *, 0)	1	1	0
(1, 1, *, 1)	1	1	0

(41)

$$I_{\phi}(3) = I_{\phi}(4) = \frac{1}{8}[0 + 0 + 0 + 0 + 0 + 1 + 0 + 0] = \frac{1}{8} \quad (42)$$

For the system in Figure 2, component 3 (and also by symmetry, component 4) has structural reliability importance equal to $\frac{1}{8}$. This means that there is only one configuration out of the eight possible in which it matters whether component 3 is working. This is the case where $x_1 = 1$, $x_2 = 0$, and $x_4 = 1$. In all

seven of the other cases, it does not matter whether component 3 works or fails; the state of the system will be the same.

Relationship between Reliability Importance and Structural Reliability Importance

We saw in the section titled “Examples” that the reliability importance can be written as

$$I(k) = r(1_k, \mathbf{x}) - r(0_k, \mathbf{x}) \quad (43)$$

If all components except component k have reliability $\frac{1}{2}$, and if components act independently, then all 2^{n-1} possible configurations are equally likely and have probability $1/2^{n-1}$. If $\mathbf{X}$ denotes the random state vector, then we can write

$$E[\phi(1_k, \mathbf{X}) - \phi(0_k, \mathbf{X})] = \sum_{\{\mathbf{x}: x_k=1\}} \frac{1}{2^{n-1}} [\phi(1_k, \mathbf{x}) - \phi(0_k, \mathbf{x})] = I(k) \quad (44)$$

Thus, for the special case of $p_i = \frac{1}{2}$, $i \neq k$, the structural reliability importance and the reliability importance coincide.

Modules and Modular Decomposition

Introduction

In engineering terminology, a *module* is simply a cluster of components that is treated as a single entity in a system. For example, an engine is often treated as a module in the airline industry. If an engine has failed or has signs of serious **degradation**, it is taken off the airplane as a whole and sent to the engine manufacturer for repair and/or rebuild. A self-contained assembly of electronic components and circuitry such as video card, a hard disk, or a motherboard is also referred to as a module. In software engineering, a module is defined as a software entity that groups a set of subprograms and data structures. These software modules are units that can be compiled separately, which makes them reusable and allows multiple programmers to work on different modules simultaneously. A module may also be an integrated unit including both hardware and software.

In system reliability theory, a module represents a group of components that has a single input from and a single output to the rest of the system in the system's reliability block diagram (*see Coherent Systems*). The state of the module can be represented by a random variable. The contribution of all components in a module to the performance of the whole system can be represented by the state of the module. Once the state of the module is known, one does not need to know the states of the components within the module to determine the state of the system. If we know the reliabilities of the modules in a system, we can use them to find the reliability of the system.

With the advancement of technology, today's engineering systems are becoming more and more sophisticated. For example, a spacecraft may consist of millions of components. In design optimization of such a system subject to budget, reliability, physical weight, and other constraints, efficient reliability evaluation algorithms are needed. Appropriate identification of modules within a system and use of modular decomposition will enhance the efficiency of system reliability evaluation and, as a result, that of design optimization.

In this article, we will provide the formal definitions of modules and modular decomposition for system reliability analysis, illustrate the technique of modular decomposition, and outline reliability evaluation algorithms for several well-studied modules. References for further reading in this area will also be provided. Unless otherwise stated, we adopt the following assumptions in this article:

1. The systems to be discussed are coherent systems (*see Coherent Systems*).
2. The system and its components may be in only two possible states, either working or failed.
3. The states of the components are independent random variables.
4. The mission time of the system is implicitly specified.

On the basis of these assumptions, we deal primarily with system and component reliabilities rather than their reliability functions of time t .

Definitions and General Guidelines

In reliability analysis, a *system* is defined as a set of components that work together to perform a specific function. The reliability of the system is determined by the reliabilities of its components and how the components are logically connected together to form the system. If there exists a subset of components in the system which work together to perform a sub-function of the system, we say that this subset of components forms a subsystem. The reliability of this subsystem is completely determined by its components and how they are logically connected together to form the subsystem. In reliability evaluation of the original system, if we can treat this subsystem as a single "component" with a reliability value of the subsystem and the reliability of the system obtained this way is the same as that obtained when all the components of the subsystem are explicitly considered, then we say that this subsystem of components is actually a "module". This is an intuitive explanation of what a module is. If we use the definition of a coherent system (see Barlow and Proschan [1]), a module can be explained to be a subset of components which form a coherent system structure such that the system as a whole is coherent even if the components in the module are treated as a single

2 Modules and Modular Decomposition

“component”. The formal definition of a module is given below.

Definition 1 (Barlow and Proschan [1]) The coherent system (A, χ) is a module of the coherent system (C, ϕ) if $\phi(\mathbf{x}) = \psi(\chi(\mathbf{x}^A), \mathbf{x}^{A^c})$, where ψ is a coherent structure function, A is a subset of C , A^c is the subset of C that is complementary to A , and $\mathbf{x}^A$ is a vector representing the states of the components in set A . The set $A \subseteq C$ is called a modular set of (C, ϕ) .

On the basis of this definition, each component by itself is a module of the system. The system itself can also be considered to be a module. However, these two extreme cases do not provide any advantage in system reliability evaluation.

If A is a module, A^c must be a module too. If a module A has been identified in a system, we can say that the system has been decomposed into two modules, A and A^c . The system can be considered as consisting of these two modules. Each module has a structure function. The structure function of the system can be expressed as a function of the structure functions of the two modules.

More than two modules may exist in a coherent system. Modular decomposition is a technique that can be used to decompose a coherent system into several disjoint modules. Such a decomposition is useful if the structure function of each module can be easily derived and the structure function relating the system state to the states of these disjoint modules can be easily derived. A formal definition of modular decomposition is given below.

Definition 2 (Barlow and Proschan [1]) A modular decomposition of a coherent system (C, ϕ) is a set of disjoint modules, $\{(A_1, \chi_1), (A_2, \chi_2), \dots, (A_r, \chi_r)\}$ together with an organizing structure ψ such that

$$C = \bigcup_{i=1}^r A_i, \text{ and } A_i \cap A_j = \emptyset \text{ for } i \neq j \quad (1)$$

$$\phi(\mathbf{x}) = \psi[\chi_1(\mathbf{x}^{A_1}), \chi_2(\mathbf{x}^{A_2}), \dots, \chi_r(\mathbf{x}^{A_r})] \quad (2)$$

To apply the modular decomposition technique in the derivation of system structure functions, we need to identify disjoint modules within the system structure. The structure function of each disjoint module must be easy to derive. These modules can

then be treated as “supercomponents” or subsystems, and we only need to find the relationship between the state of the system and the states of these modules. Hopefully, the number of such modules is much smaller than the number of components in the system.

We may use the following two approaches individually or in combination to identify modules in a complex system. The first approach defines modules based on a clear understanding of the functions of some components in the system. For example, in a chemical refinery, a primary pump is used to provide the required flow rate and pressure of a certain liquid. A secondary pump is installed as a cold standby unit. These two pumps together with their auxiliary instruments such as the sensing and switching mechanism can be called the *pump module*. The reliability of the pump module can be derived using the standby structure and used in further evaluation of the chemical refinery’s reliability. Another example is a power system including generation, transmission, and distribution subsystems. A single power station including several generators may be considered to be a module if all these generators use a single point of delivering power to the transmission network. This module of generators may have a *k-out-of-n* structure (see *k-out-of-n Systems*).

The second approach assumes that the reliability block diagram of the system has already been developed. From the system reliability block diagram, we then identify modules following Definition 1. We will illustrate the technique of modular decomposition using this second approach in the section titled “Modular Decomposition”.

Well-studied modules include the series structure, the parallel structure, the series–parallel structure, the parallel–series structure, the bridge structure, the *k-out-of-n* structure, the standby structure, and the consecutive-*k-out-of-n* structure. Efficient reliability evaluation algorithms have been reported for these modules. These modules will be further elaborated in the section titled “Well-Studied Modules”.

In subsequent discussions, the following notation will be used:

p_i : reliability of component i

q_i : unreliability of component i ,

$$q_i = 1 - p_i$$

R_a : reliability of a where

a is a string of letters or

numerals that may represent

a module or subsystem or the system

$Q_a : 1 - R_a$.

Modular Decomposition

Consider the reliability block diagram depicted in Figure 1(a). The nine components are numbered from 1 to 9. We are interested in finding the reliability of this system.

Examining Figure 1(a), we can identify the following modules:

- Module I consists of components 1 and 2 connected in series.
- Module II consists of components 3 and 4 connected in series.
- Module III consists of components 6, 7, and 8, wherein components 7 and 8 connected in parallel form a submodule which is then connected to component 6 in series.

The three modules listed above are the only meaningful modules in Figure 1(a) that may be used for efficient evaluation of system reliability. They are the only clusters of components that have a single input from and a single output to the rest of the system in the reliability block diagram. The

reliabilities of these modules are

$$R_I = p_1 p_2 \quad (3)$$

$$R_{II} = p_3 p_4 \quad (4)$$

$$R_{III} = p_6(1 - q_7 q_8) \quad (5)$$

With these identified modules, the system reliability block diagram shown in Figure 1(a) is transformed into the one shown in Figure 1(b). This resulting reliability block diagram is actually called the *bridge structure*.

If direct identification of known modules does not yield a simple organizing structure for system reliability evaluation, there are other techniques one may apply for further identification of modules. These techniques include the so-called pivotal decomposition, Δ -star transformation, and star- Δ transformation. For details on these techniques, readers may refer to Kuo and Zuo [2] and Misra [3].

Well-Studied Modules

Many special system structures have been studied by researchers. Efficient reliability evaluation algorithms have been reported for these structures. In this section, we call these special structures modules and provide their definitions and reliability evaluation algorithms (*see Parallel, Series, and Series-Parallel Systems; k-out-of-n Systems*).

Any n components connected in series form the *series module*. The reliability of a series module can be calculated as

$$R_{\text{series}} = p_1 p_2 \cdots p_n \quad (6)$$

Any n components connected in parallel form the *parallel module*. The reliability of a parallel module can be calculated as

$$R_{\text{parallel}} = 1 - q_1 q_2 \cdots q_n \quad (7)$$

A parallel-series system can be considered to consist of m disjoint modules that are connected in parallel and module i ($1 \leq i \leq m$) consists of n_i components that are connected in series. If the number of components in each of the m modules is not too large and m is not too large, the whole parallel-series system may be considered to be a module. The reliability of such a *parallel-series*

Figure 1 Illustration of modular decomposition

4 Modules and Modular Decomposition

module can be expressed as

$$R_{\text{parallel-series}} = 1 - \prod_{i=1}^m \left(1 - \prod_{j=1}^{n_i} p_{ij} \right) \quad (8)$$

where p_{ij} is the reliability of component j in series module i for $1 \leq i \leq m$ and $1 \leq j \leq n_i$.

A series-parallel system can be considered to consist of m disjoint modules that are connected in series and module i ($1 \leq i \leq m$) consists of n_i components that are connected in parallel. If the number of components in each of the m modules is not too large and m is not too large, the whole series-parallel system may be considered to be a module. The reliability of such a *series-parallel module* can be expressed as

$$R_{\text{series-parallel}} = \prod_{i=1}^m \left(1 - \prod_{j=1}^{n_i} q_{ij} \right) \quad (9)$$

where q_{ij} is the unreliability of component j in parallel module i for $1 \leq i \leq m$ and $1 \leq j \leq n_i$.

A standby structure can also be considered to be a module. Consider a *standby module* with a primary unit and one cold standby unit. There is a sensing and switching mechanism that switches the standby unit into operation when it detects the failure of the primary unit. To evaluate the reliability of such a module, one needs to know the lifetime distribution function of each unit. Under the assumptions that each component being used follows the exponential lifetime distribution with parameter λ , the standby unit is perfect, and the sensing and switching mechanism is perfect, the reliability function of the module can be expressed as

$$R_{\text{standby}}(t) = e^{-\lambda t} (1 + \lambda t) \quad (10)$$

With this equation, one can evaluate the reliability of the module for any specified mission time t . For more advanced analysis of the standby module under more relaxed conditions, readers are referred to Kuo and Zuo [2].

The reliability block diagram of the bridge structure is shown in Figure 2. It can be called the *bridge module*. The reliability of this module can be expressed as

$$R_{\text{bridge}} = p_3(1 - q_1q_4)(1 - q_2q_5) + q_3 \times [1 - (1 - p_1p_2)(1 - p_4p_5)] \quad (11)$$

Figure 2 The bridge module

The k -out-of- n structure may also appear in a sophisticated reliability system. A k -out-of- n system works if and only if at least k of the n components work. A recursive formula for reliability evaluation of such a k -out-of- n module is given by Rushdi [4] as follows:

$$R(k, n) = p_n R(k-1, n-1) + q_n R(k, n-1) \quad (12)$$

where $R(a, b)$ denotes the probability that at least a components out of the b components work. The boundary conditions for equation (12) are

$$R(0, j) = 1, \quad j \geq 0 \quad (13)$$

$$R(j+1, j) = 0, \quad j \geq 0 \quad (14)$$

It would be advantageous to treat a k -out-of- n structure as a module in a complex system for its reliability evaluation only if the number of components in the k -out-of- n structure is not too large.

A consecutive- k -out-of- n system consists of linearly arranged components and it is failed if and only if at least k consecutive components are failed. Such a system structure may appear as a module in a sophisticated system. An efficient recursive equation is provided by Hwang [5] for reliability evaluation of such a *consecutive- k -out-of- n module*:

$$R_c(k, n) = R_c(k, n-1) - R_c(k, n-k-1) \times p_{n-k} \prod_{j=n-k+1}^n q_j \quad (15)$$

where $R_c(a, b)$ is the probability that at least a consecutive components have failed among the first b components. The boundary conditions for equation (15) are

$$R_c(a, b) = 1, \quad b < a \quad (16)$$

$$p_0 \equiv 0 \quad (17)$$

Advanced coverage of the consecutive- k -out-of- n structure and its variations can be found in Chang *et al.* [6].

Summary and Further Reading

A key step in modular decomposition is the definition of modules. Each identified module should be simple enough to enable us to obtain its various reliability characteristics relatively easily. Consider the example reliability block diagram given in Figure 3. There are 10 components in the system. One option is to decompose the system into three modules with module I including components 1 through 4, module II including components 5 through 7, and module III including components 8 through 10. Module I has a parallel structure, module II has a series-parallel structure, while module III has a 2-out-of-3 structure. The organization structure of the system consisting of these three modules is a series structure.

To evaluate a large and complex reliability system, we often have to apply the so-called hierarchical modular decomposition. The system is decomposed into modules (this is called the *level 1 decomposition*). Each module in the system may be further decomposed into submodules (this is called the *level 2 decomposition*). The process continues until the modules or submodules in the lowest level of decomposition are simple enough.

The technique of modular decomposition can be used not only to evaluate the exact system reliability but also to derive bounds on system reliability. This can be achieved through hierarchical modular decomposition. Starting from the lowest decomposition level, we first find the bounds on the reliabilities of all the modules at this level. Once these bounds are obtained, these modules at the lowest level are treated as supercomponents with known reliability bounds. Higher-level modules consisting of these supercomponents are then analyzed. Bounds

on these higher-level modules may be obtained. This process is repeated until we reach the system level wherein the upper and/or lower bounds on the system reliability can be obtained from the bounds of its immediate modules. As illustrated by Barlow and Proschan [1], utilization of modular decomposition can improve the bounds obtained.

The modules summarized in this article are widely seen in engineering systems. The series, parallel, parallel-series, and series-parallel modules are most commonly seen. The bridge module is used in networks. The standby module is often used in mechanical systems. The k -out-of- n module is seen in modeling power generation stations and the triple-modular redundancy (TMR) and N -modular redundancy (NMR) schemes in software engineering and fault tolerance control (see Hecht [7], Xie *et al.* [8]), and N -version programming (NVP) (see Avizienis [9]). The consecutive- k -out-of- n module has been used in modeling pipeline transportation systems (see Chang *et al.* [6]).

Advanced studies of the k -out-of- n and the consecutive- k -out-of- n modules can be found in Chang *et al.* [6], Kuo and Zuo [2], and Lisnianski and Levitin [10]. Both components and the system may assume binary states or multiple states (more than two states). There may be common-cause failures. The system and the components may be repairable or nonrepairable. Other reliability characteristics such as mean time to failure (MTTF), mean time between failure (MTBF), and availability have also been studied. Another topic involving modules that has been well studied is the assembly of components into different modules of a system. This involves allocation of components having different reliabilities to different modules within the system. El-Newehi *et al.* [11] provided optimal allocations of components to parallel-series and **series-parallel systems**. Du and Hwang [12] provided optimal allocations of components to an s -stage k -out-of- n system, in which the system can be hierarchically decomposed into s stages and each stage has the k -out-of- n system structure.

Repairable Systems Reliability

Introduction

We begin by defining a repairable system, after some preliminary concepts and definitions.

1. *Part*: an item not subject to disassembly and hence discarded when it fails.
2. *Socket*: a circuit or equipment position which, at any given time, holds a part of a given type.
3. *System*: a collection of two or more sockets and their associated parts, interconnected to perform one or more functions.
4. *Nonrepairable System*: a system that is discarded the first time that it ceases to perform satisfactorily.
5. *Repairable System*: a system which, after failing to perform at least one of its required functions, can be returned to performing all of its required functions satisfactorily by any method other than replacement of the entire system.

Three points must be made. First, since small appliances are systems, many systems, perhaps even a majority, are nonrepairable. Nevertheless, the overwhelming majority of systems of interest in reliability applications are designed to be repaired, rather than discarded, after their first failure. Henceforth, therefore, the term *system* will be used to denote a repairable system.

Secondly, given that a system contains n parts, the definition of a repairable system allows up to $n - 1$ part replacements during a single repair. In practice, however, when the repair would require many new parts, it usually is more cost effective to replace the entire system. Most repairs involve the replacement of only a minute fraction of a system's constituent parts and this has major implications for probabilistic modeling and therefore, for statistical analysis as well. Some repairs, e.g., cleaning contacts or adjusting internal potentiometers, do not involve replacement of any parts.

Thirdly, if a system can be returned to satisfactory operation by "occasional" adjustments of external, i.e. "front panel" controls, it hasn't failed and therefore, doesn't require repair. However, "too frequently"

required adjustments necessitate repair to reduce the rate of such adjustments.

Probabilistic Modeling

Most of the literature concerning methods for predicting the time to failure of a system assumes that system failure is an absorbing state, i.e., that the system of interest is nonrepairable. In many cases, the nonrepairable system can include one or more groups of repairable redundant subsystems. Once a system-level failure occurs, however, the system is assumed to be discarded. Such "reliability with repair" models will not be considered in this article.

This section concentrates on "black-box" modeling and analysis. That is, models are postulated for the pattern of system-level failures, regardless of the system's design, and the postulated models can be tested against even small datasets.

Model for Parts

The time to failure of a part is a random variable, X , described either with the cumulative distribution function

$$F_x(x) \equiv \Pr\{X \leq x\} \quad (1)$$

or the force of mortality (FOM)

$$h_x(x) \equiv \frac{F'_x(x)}{1 - F_x(x)} \quad (2)$$

Intuitively, $h_x(x)$ measures how likely it is that *one* failure will occur soon after time x , given that *it* has not occurred by time x .

Model for Systems

The failures of a system are described by a stochastic point process $T_1, T_2, \dots$, where T_i denotes the arrival time to the i th failure, measured from the instant at which a system was first put into operation. Equivalently, the process can be represented by the interarrivals times, $X_1, X_2, X_3, \dots$, where $X_i \equiv T_i - T_{i-1}$ and $T_0 \equiv 0$. Downtimes, usually very small compared to most interarrivals times, are ignored throughout, except for a brief mention in the section titled "Misconceptions and their Causes".

Let $N(t)$ be the observed number of system failures in the interval $(0, t]$. The expected number

2 Repairable Systems Reliability

of failures is $V(t) \equiv E[N(t)]$. The rate of occurrence of failures (ROCOF) is defined as

$$v(t) \equiv \frac{d}{dt} E[N(t)] \quad (3)$$

The ROCOF is an absolute rate, whereas the FOM is a relative rate. Hence, even though ROCOF and FOM can be, and sometimes must be, represented by the same mathematical function, with numerically equal parameters, the section titled “Misconceptions and Their Causes” shows that they have up-to-infinitely different interpretations.

We will consider only the homogeneous **Poisson process** (HPP) and some generalizations of it: the renewal process (RP), the superimposed renewal process (SRP), and the nonhomogeneous Poisson process (NHPP). The HPP can be defined as a *nonterminating sequence of exponential interarrivals times* which are independent and identically distributed (i.i.d.). The ROCOF of an HPP is a constant for all $t \geq 0$. The RP is a direct generalization, since the i.i.d. interarrivals times can be distributed according to any nonnegative distribution.

Consider two or more independent RPs, each of which represents the pattern of failures in a socket. Then the union of all failures, including the instants at which they occurred, is an SRP. In general, the SRP is not an RP; in fact, if the superposition of two independent RPs is an RP, then all three are HPPs [1].

For a formal definition of an NHPP, (see **Intensity Functions for Nonhomogeneous Poisson Processes**). Here, an NHPP can be considered to be any process where the ROCOF is a nonnegative deterministic function of time, independent of the history of the process.

Most repairs involve replacement of only a minute fraction of a system’s parts. It is very implausible, therefore, to assume the RP as a model, i.e. to assume that a system’s effective age is reduced to zero by every repair. In fact, under the universal engineers’ and laymen’s usage of the term *repair*, a well-performed repair returns a failed system to satisfactory performance, without *even intending* to reduce its age to zero. Nevertheless, the RP is often assumed to be *the* model for a system; see, e.g., [2, 3].

A plausible system model can be developed by assuming renewal in each of the system’s sockets. After all, the failed part in the socket is replaced with a new one. Given an RP for each socket, and a

series system, the resulting model is the SRP. There may be cases where one can work with an SRP directly, but usually an approximation is needed. The model for a finite number of superimposed **renewal processes** is unknown, but there are limit theorems (see [4]) indicating that when the number n of sockets in a series system increases without bound, the SRP converges to an NHPP. (If, in addition $t \rightarrow \infty$, then the SRP converges to an HPP [5].)

Many systems have some redundant paths, so it might appear that the NHPP approximation would not apply to them. However, the series parts often dominate the system’s reliability, so that redundant paths often can be ignored in developing the $SRP \rightarrow NHPP$ model.

A more pragmatic way of “deriving” the NHPP as the first-order system model is to imagine someone trying to sell you a used car. The first things you want to know are the total miles/kilometers on the odometer and the year the car was manufactured. Since each of these measures is independent of its failure/repair history, the universal first-order model for a car is the NHPP. You also want to know about major repairs and overhauls, so this model is not “exact”. However, the RP, which often is claimed to be *the* system model, is absurd in this scenario; if a salesman tried to convince you that a 10-year-old car was only 2 days old because it had been repaired 2 days earlier, you would seek a car elsewhere!

The HPP (usually and erroneously called *exponentiality* by both practitioners and theorists) is often portrayed as *the* system model, based on Drenick’s [6] asymptotic theorem. However, systems often do not operate long enough to have such asymptotic results hold, even to a reasonable approximation. For example, a 10-year-old car modeled by an HPP would have no effective age, not even the 2 days since the last repair. The salesman, therefore, could claim that it was “brand new”!

Fortunately, the NHPP is a very tractable model as well. For example, the superposition of independent NHPPs (SNHPP) is an NHPP, so – unlike the RP – the model for the SNHPP is known. In addition, the NHPP is much more tractable than the RP or the SRP.

The NHPP is not an exact model for a system, but it often is a good working approximation. Even far more complicated models ignore most – or all – of the 18 shortcomings of probabilistic modeling of systems listed in [7].

Statistical Analysis

The interarrivals times between failures of a system appear in natural order on a time line. The *first* step in an analysis, therefore, is to test for trend. If a trend toward larger interarrivals times (**reliability growth** or improvement) or toward smaller interarrivals times (deterioration) exists, the interarrivals times are not identically distributed. Hence, little or nothing in many reliability and statistics books is applicable, since many books concentrate solely on i.i.d. data. If an assumption is dropped, it usually is that of independence, rather than the even more important assumption of identically distributed interarrivals times.

Parametric Models

Given a trend, the NHPP is the first choice as a model. Consider the power-law process where $v(t) = \gamma\beta t^{\beta-1}$.

Then if failures occurred at arrival times $T_1 = t_1, T_2 = t_2, \dots, T_m = t_m$, over an observation interval $(0, t^*]$, the maximum-likelihood estimators (MLEs) of β and γ are

$$\hat{\beta} = \frac{m}{\sum_{i=1}^m \ln(t^*/t_i)} \quad (4)$$

$$\hat{\gamma} = \frac{m}{\hat{\beta} t^*} \quad (5)$$

If observation is till time T_m , then T_m is substituted for t^* in both equations. Many other techniques for the power-law process and other NHPPs are provided in [8] and the references therein. Lawless and Thiagarajah [9, 10] show how to include explanatory factors or covariates, e.g. different environmental stresses experienced by different system copies, in an analysis.

If there is no evidence of trend, the data can be considered to be identically distributed, but the interarrivals times of a copy may still be dependent. In practice, however, one seldom has enough failures to test the independence assumption [11].

If there is no evidence that the interarrivals times are not i.i.d., one fits an RP to them. If an exponential distribution provides adequate fit, the resulting model is the HPP; otherwise, a more general RP must be selected. The techniques (a) for fitting an exponential distribution to times to failure of parts and (b) for

fitting an HPP to system interarrivals times are interchangeable. The *interpretations* of the results, however, often are drastically different. This is because a failed part is discarded at failure, whatever the magnitude of its constant FOM, whereas a failed system modeled by an HPP is repaired to the ROCOF it had when it was new, which may be very large. For further information on the major differences in interpretations, see [12, 13.]

Nonparametric Models

Cumulative Plots. If we plot cumulative failures *versus* cumulative operating time, t , for a single system copy, we can perform trend testing visually. An increasing, constant, or decreasing slope is an indication of deterioration, noncommittal, or improving reliability, respectively, of that system copy. Deteriorating (improving) systems have become known as *sad* (*happy*) systems to help distinguish these concepts from wear out (**burn-in**) of parts.

Mean Cumulative Function. In most applications, data are available from two or more copies and in many cases the number of copies is far greater than two. The mean cumulative function (MCF) is constructed incrementally at each instant a failure occurs by considering the number of copies at risk at that instant. Copies may not be in the risk set because of left or right censoring. Left censoring occurs when a copy is operated for some time without knowledge of its failure history and then comes under observation. Right censoring occurs when a copy is no longer observed after a time $t = t^*$ for any reason, ranging from the copy being “totaled” to simply not accumulating more than t^* hours at a time when the number at risk is being calculated. The key reference to this approach is [14].

Misconceptions and Their Causes

When parts are tested to failure, the i.i.d. assumptions are plausible and greatly simplifying. When the times between successive failures in a socket are analyzed, the i.i.d. assumptions, leading to the RP, are plausible but no longer tractable. For a system, the RP is neither plausible nor tractable *nor even desirable*; one hopes that successive interarrivals times tend to become larger, e.g., through reliability growth testing

or from improved operating/maintenance procedures. It is amazing, therefore, that some reliability texts still totally ignore **repairable systems** or assume that the RP is *the* only model for such a system. Many texts do not provide techniques for testing for nonstationarity and do not even hint that such trend tests are essential.

Even when the RP is not assumed to be the universal system model, sometimes it seems to be assumed, when it is not. For example, [15] does not restrict itself to the RP, but also uses the word *renewal* as a synonym for repair. Hence a “renewal” may return a system to the same-as-new condition of an RP – but it may also leave the system in *some other condition* after the repair. As discussed in [13], renewal sometimes is infinitely better described as “bad as new”, rather than the virtually universally used term, *good as new*.

It is widely believed, even among theorists, that it is too difficult to apply nonstationary models. However, the NHPP is much more tractable than the RP. For example, the renewal function, i.e. the expected number of failures over $(0, t]$, is unavailable in closed form, except for a few special cases; the corresponding quantity under an NHPP is $\int_0^t v(z) dz$, and one selects a function for v , for which the integral is known. Or, compare the simple MLE, equation (4), for the shape parameter of the power-law process with the messy transcendental MLE equation for the shape parameter of the Weibull distribution, which must be solved by trial and error.

It is also widely believed that an RP whose distribution has increasing (decreasing) FOM can model deterioration (improvement) of a system. The main reason for this misconception is that the FOM, $h_x(x)$, is usually called *failure rate*, especially by theorists. A natural interpretation of “increasing failure rate” is an increasing number of failures per unit time, see e.g. [16], but increasing FOM does *not* imply that. Consider, for example, the model for a system where $X_i \sim U(0, i]$, $i = 1, 2, 3, \dots$. Then each X_i has an FOM which strictly increases from i^{-1} to infinity, but the number of system failures per unit time decreases asymptotically to zero as $i \rightarrow \infty$. Even for parts that are tested to failure, increasing FOM does *not* imply an increasing number of part failures per unit time. (Consider a group of a million people all born in say, 1907. By now the number of deaths per year is stochastically *decreasing* rapidly since very few from the original million are still at risk of dying.)

The FOM should not be called *failure rate*, to avoid assigning flagrantly counterintuitive meanings to the misnomer “failure rate”.

There are other reasons for confusion between FOM and ROCOF. For example, under an NHPP the ROCOF of the process is equal to – but not equivalent to – the FOM of the distribution of time to first failure of the process. Therefore, under an HPP both FOM and ROCOF are equal to the same constant. However, when the area under any FOM increases to infinity, one failure will occur with probability one. In infinite contrast, when the area under any ROCOF increases to infinity, the expected number of failures increases to infinity. Hence, it is essential to distinguish between FOM and ROCOF, rather than to emphasize their superficially striking – but relatively unimportant – similarities.

Confusion about the distinction between FOM and ROCOF has led to the erroneous belief that there is only one bathtub curve. In the bathtub curve for parts, FOM is plotted against part age x . In the curve for a system, ROCOF is plotted against the total operating time t of the system, regardless of whether one or more failures have occurred. In practice, both curves usually are depicted as $\lambda(t) = \text{“failure rate”}$ plotted against “ t ”. This makes it impossible to tell which bathtub curve is portrayed just from the plot. Some authors refer to only one of these interpretations, and some refer to both as if they were equivalent, see e.g. [17]. In many cases, however, widespread poor and incorrect terminology and notation make it *impossible* to ascertain *which* bathtub curve is being discussed, even from the text accompanying the plot.

One further point about the system bathtub curve: the increasing ROCOF for large t implies that $v(t) \rightarrow \infty$ as $t \rightarrow \infty$. On the other hand, asymptotic theorems such as Drenick’s imply that $v(t)$ approaches a finite constant as $t \rightarrow \infty$. Theorists use the asymptotic theorems to justify the HPP, whereas practitioners erroneously assume that the bottom of the system bathtub curve implies an HPP. Neither group is aware of the other’s rationale.

For a system the interarrivals times are the times between failures. For parts, the spacings between order statistics *also* can be interpreted as “times between failures”. Moreover, when parts are put on test (or into operation) simultaneously and run continuously, their “times between failures” appear *exactly* in real time; because of nonzero repair times, this is never exactly true for the interarrivals times of

systems. It is essential to clearly distinguish between the two kinds of “times between failures”.

Most of the listed misconceptions and inherent ambiguities, but especially the use of the misnomer, “failure rate” for both FOM and ROCOF, caused great confusion in [18], as acknowledged in [19]. For example, two obviously different plots obtained from the same failure numbers, one actually estimating FOM and the other actually estimating ROCOF, were claimed to be plots of the *same* “failure rate”. Ascher [20] summarized the problem and its causes and showed how Juran and Gryna [21] also confused themselves by using the term *failure rate* interchangeably for both FOM and ROCOF.

The many inherent ambiguities in analyzing repairable systems failure data make it essential to avoid avoidable ambiguities, such as (a) using “*t*” for both the age of a part and for the total operating time of a system and (b) using “failure rate” for both FOM and ROCOF. Unfortunately, to the present writing, most practitioners have followed the lead of most theorists in embracing both types of ambiguities.

Reliability of Redundant Systems

Introduction

Redundancy models have been a part of reliability theory almost since the inception of reliability theory. Perhaps the simplest reliability with redundancy model is the dynamic redundancy model. A dynamic redundant system often consists of several modules but with only one module that is required to operate at a time for the system to function. Various fault detection schemes are used to determine when a module has become faulty, and the fault location is used to determine exactly which module, if any, is faulty. If a fault is detected and located, the faulty module is removed from operation and replaced by a spare. The section titled “Dynamic Redundant Systems” discusses various dynamic redundant systems, including fault detection and fault recovery, noncoherent and dual working modes. The section titled “Redundant Systems with Multiple Failure Modes” discusses redundant systems with multiple failure modes, and finally in the section titled “Load-Sharing Redundant Systems”, a brief load-sharing redundant system will be discussed.

Dynamic Redundant Systems

Systems with Imperfect Coverage

Suppose the system consists of $(S + 1)$ modules where S is the total number of spare modules. The modules could be a processor in a multiprocessor system, a generator in an electrical power system, or a logic gate. Examples of duplex (when $S = 1$) configurations are the UDET 7116 telephone switch system [1], the COMTRAC railway traffic controller [2], and the Bell ESS [3]. It is assumed that the lifetimes of the modules are independent and identically distributed (i.i.d.), both modules and the system are of two states, i.e., either successful or unsuccessful (failed) and the reliability of each module, active or spare, is p . The reliability of the dynamic redundant system with S spares is given by

$$R(S) = 1 - (1 - p)^{S+1} \quad (1)$$

The above reliability function is obtained assuming that the fault detection and the switch-over mechanism are perfect. This implies that the function $R(S)$ is, of course, an increasing function of the number of spare modules. On the one hand, adding spare modules makes it more likely that the reliability of the system will increase, but on the other hand, and in practice, the dynamic redundant system may not be able to use the redundancy because it cannot identify that a module is faulty, remove that fault module, and replace it with a fault-free one.

Let f be the probability that the fault detection and switching mechanisms operate correctly, given the failure of one of the modules. The reliability of a dynamic redundant system with fault coverage is given by

$$R_f(S) = \sum_{i=1}^{S+1} \binom{S+1}{i} p^i [(1-p)f]^{S+1-i} \quad (2)$$

It can be shown that [4], for fixed p and f , the maximum value of $R_f(S)$ is attained at $S^* = \lfloor S_1 \rfloor + 1$ where

$$S_1 = \frac{\ln \left(\frac{(1-p)(1-f)}{1-(1-p)f} \right)}{\ln \left(\frac{(1-p)f}{p+(1-p)f} \right)} \quad (3)$$

If S_1 is an integer, S_1 and $S_1 + 1$ both maximize $R_c(S)$.

Fail-Safe Redundancy

This section discusses a fail-safe system (FSS) consisting of a fail-safe redundancy (FSR) core with an associated bank of S spare units in which when one of the $(N - 1)$ operating units fails, the redundant unit immediately starts operating [5]. The failed unit is then replaced by a spare, which then becomes the new redundant unit restoring the FSR core to the all-perfect state. The system survives provided at least $(N - 1)$ out of $(N + S)$ i.i.d units are operable. Applications of such systems can be found in the areas of safety monitoring and reactor trip function systems. For example, in the areas of safety monitoring systems, nuclear plants often use three identical and independently functioning counters to monitor the radioactivity of the air in ventilation systems, with the aim to initiating reactor shutdown

2 Reliability of Redundant Systems

when a dangerous level of radioactivity is present. When two or more counters register a dangerous level of radioactivity, the reactor automatically shuts down.

Suppose that each unit costs c dollars and a system failure costs d dollars. The average total system cost $E(T_s)$ is

$$E(T_s) = c(N + S) + d[1 - R(S)] \quad (4)$$

where the reliability of FSS is

$$R(S) = \sum_{i=N-1}^{N+S} \binom{N+S}{i} p^i (1-p)^{N+S-i} \quad (5)$$

and p is a unit reliability. The average total system cost of system size $(N + S)$ is the cost incurred when the system has failed plus the cost of all $N + S$ modules.

Pham and Galyean [5] show that for given values of p , N , d , and c , the optimal value S^* such that the FSS minimizes the average total system cost is as follows:

- (1) if $f(S_0) < A$ then $S^* = 0$
- (2) if $f(S_0) \geq A$ and $f(0) \geq A$ then $S^* = S_a$
- (3) if $f(S_0) \geq A$ and $f(0) < A$ then

$$S^* = \begin{cases} 0 & \text{if } E(T_0) \leq E(T_{S_a}) \\ S_a & \text{if } E(T_0) > E(T_{S_a}) \end{cases} \quad (6)$$

where

$$S_0 = \max \{0, [S_1] + 1\}; \quad (7)$$

$$S_1 = \frac{(N+1)(1-p) - 3}{p}; \quad (8)$$

$$A = \frac{c}{dp^{N-1}(1-p)^2}; \quad (9)$$

$$S_a = \inf \{S \in [S_0, \infty): f(S) < A\} \quad (10)$$

$$f(S) = \binom{N+S}{S+2} (1-p)^S \quad (11)$$

Consider a cooling water system for a commercial nuclear power plant (either service water or component cooling) typically consisting of a two-drain system, each with a dedicated pump. The system will usually have a third “swing” pump that provides an automatic backup to either of the two

trains. Failure to maintain both cooling water trains operating cold will result in a plant shutdown and require the utility to buy replacement power at a cost of \$1 000 000 per day. The cost of a redundant pump is estimated at \$20 000. The constant failure rate (from random, independent faults) of the pumps is estimated at $\lambda = 10^{-4} \text{ h}^{-1}$, a 30-day pump postulated system failure (i.e., failure of the second pump), if it were to occur, is assumed midway in the replacement/repair time of the first failed pump (i.e., $T_r/2$), and would result in the plant being shut down for 15 days. In this example, we obtain $N = 3$ pumps, $c = \$20\,000/\text{pump}$, $d = \$1\,000\,000 \times 15 \text{ days} = \1.5×10^7 ; $\lambda = 10^{-4} \text{ h}^{-1}$; $T_r = 30 \text{ days}$; $p = e^{-\lambda T_r} = 0.93$.

This can be easily shown as $S^* = 1$.

A Noncoherent System

A k -to- l -out-of- n system is a noncoherent system in which “no fewer than k and no more than l ” out of its n components are to function for the successful operation of the system. This class of noncoherent systems was first proposed by Heidtmann [6]. A noncoherent system is any system that is not coherent; a system is coherent if and only if: (a) it is good (bad) when all components are good (bad), and (b) it never gets worse (better) when the number of good components increases (decreases). Such a system is noncoherent because the system reliability can decrease when the number of good components increases. The generality of the k -to- l -out-of- n system can be demonstrated as follows: (a) when $k = l = n$, the k -to- l -out-of- n system becomes a series system; (b) when $k = 1$ and $l = n$, the k -to- l -out-of- n system becomes a parallel system.

The k -to- l -out-of- n system takes into account the failures caused by the underproduction of components or services and the failures that are caused by overproduction as well [7]. Examples of noncoherent systems can be found in multiprocessor and communication [8]. A multiprocessor system, for example, shares resources such as memory, input/output units, and buses among n processors. If less than k processors are being used, the system does not work to its maximum capacity and the system efficiency is poor. On the other hand, if more than l processors are being used then efficiency again is poor because of the traffic congestion caused by the too many processors in use. Both of these cases need to be avoided; this can

be accomplished by modeling the system as failed for these cases. This multiprocessor system is thus a k -to- l -out-of- n system.

Consider a system composed of n i.i.d. components; assume that both components and the system are of two states, i.e., either successful or failed and p is the reliability of component, then the reliability of the k -to- l -out-of- n system is given by

$$R(k; l, n) = \sum_{i=k}^l \binom{n}{i} p^i (1-p)^{n-i} \quad (12)$$

It can be shown that for given values of k , l , and p , there exists an optimal value n^* for n that maximizes the system reliability $R(n)$. The value n^* is given by [7] as

$$n^* = \inf \{n : f(n) < a^{l+1-k}\} \quad (13)$$

where

$$f(n) = \frac{\binom{n}{k-1}}{\binom{n}{l}} \quad (14)$$

and

$$a = \frac{p}{1-p} \quad (15)$$

Consider a computer installation where a certain number of terminals are to be connected to a noncoherent system. It is of interest to find out what is the optimal number of terminals that maximizes the mean profit of the terminal subsystem. If the number of terminals is greater than, say l , then the response time might not be tolerable, causing a loss of profit. This is overperformance of work. If, on the other hand, the number of terminals is less than, say k , then the computer is not being used to its maximum capacity. This is underperformance of work with a lower profit. Both cases are to be avoided.

The mean system profit, $M(n)$, is defined as follows [9]:

$$\begin{aligned} M(n) &= \sum_{i=0}^n \binom{n}{i} p^i (1-p)^{n-i} f_n(i) \\ &= E \{f_n(S_n)\} \end{aligned} \quad (16)$$

where

$f_n(i)$ profit when i units are functioning

S_n binomially distributed random variable with parameters p , n , and $f_n(i) < f_n(j)$ and $f_n(r) < f_n(j)$ for $0 < i < k$, $k \leq j \leq l$, $l < r \leq n$

Pham [9] showed that for fixed k , l , and p , if the profit function f_n is concave, then there is an optimal value of n such that $M(n)$ is maximized.

Given $k = 5$, $l = 8$ and the profit function

$$f_n(i) = \begin{cases} 100i & \text{for } 0 \leq i < k \\ 500 & \text{for } k \leq i \leq l \\ 500 - 10(i-l) & \text{for } l < i \leq n \end{cases} \quad (17)$$

the optimal number of units to maximize the mean system profit is given by 9 for $p = 0.9$. The mean system profit corresponding to this optimum value is 496. For a lower value of p e.g. $p = 0.7$, the optimal number of units, 11, is higher. If p is close enough to 1, then the optimal n is very close to l .

Degradable Redundant Systems with Dual Working Modes

In many practical applications with changing working environments, the reliability of the components perhaps will change subject to working conditions. In fact, there is a minimum number of units that must function to guarantee the functioning of the system, especially in fault-tolerant computing systems. Consider a network of electric generators, for example, for which at least 80% of all generators must work to ensure a certain service level of the entire station under normal working conditions, called *good mode*. However, under those stress working conditions, called **degradation mode** at least 90% of all generators must work to ensure a full service level of the station. In the latter case, owing to a higher workload of each generator, the reliability of working generator will be decreased.

Several models and methods have been proposed in the literature to evaluate the reliability of fault-tolerant systems [10, 11], degradable computing systems [12, 13], interconnected power systems [14], weighted one-failure mode models [15], two-failure modes [16, 17], and weighted two-failure modes [18]. Not much research, however, has been published on degradable systems with dual working modes. Nordmann and Pham [19] studied the degradable systems with dual working modes; however,

4 Reliability of Redundant Systems

the requirements for the number of working units in each mode are the same as the ***k-out-of-n*** systems. Differing from such existing models and formulations in the literature, Pham [20] recently has studied a degradable system with dual working modes in which he introduces an option that the *k-out-of-n* system can lead to an *m-out-of-n* system subject to a system degradation mode under a stressed condition.

In this study the degradable redundant system with dual working modes in consideration consists of *n* units. The system and the units are either in a successful state (working) or in a failed state (not working). The system operates in a good mode with probability α and in a degradation mode with probability $1 - \alpha$. For the system to be working in a good mode, at least *k* out of *n* units must work in which the reliability of the working units is p_1 . For the system to be working in a degradation mode, at least *m* out of *n* units must work with the reliability of the working units is p_2 . Units in degradation mode are generally put under more stress than under normal conditions. This generally occurs when units such as power substations have to take extra loads (i.e., more power) from other unavailable (or failed) units that fail to keep the system in a working system state. On the basis of such applications, the number of *m* working units (number of units required for the system to be working in a degradation mode) is considered to be greater than or equal to *k* (the number of units required for the system to be working in a good mode). In other words, it is assumed that $m \geq k$ and $p_1 \geq p_2$.

The system functions in a good mode if and only if a minimum number of *k* out of *n* units must work. Similarly, the system functions in a degradation mode if and only if at least *m* out of *n* units must work. The reliability of the system with dual working modes is given by [20]:

$$R(n) = \alpha \left[\sum_{i=k}^n \binom{n}{i} p_1^i (1 - p_1)^{n-i} \right] + (1 - \alpha) \left[\sum_{i=m}^n \binom{n}{i} p_2^i (1 - p_2)^{n-i} \right] \quad (18)$$

where $k \leq m \leq n$ and $p_1 \geq p_2$.

Given $k = 5, m = 7, \alpha = 0.7, p_1 = 0.5$ and $p_2 = 0.4$ for example. Table 1 presents the reliability calculations for various values of *n*.

Redundant Systems with Multiple Failure Modes

In some applications, a component can be subjected to failure in either open or closed modes [21]. Networks of relays, fuse systems for warheads, diode circuits, fluid flow valves, and so on are a few examples of such components. As discussed in previous sections, redundancy can be used to enhance the reliability of a system without any change in the reliability of the individual components that form the system. However, in a two-failure mode problem, redundancy may either increase or decrease the system's reliability. For example, a network consisting of *n* relays in parallel has the property that a closed-mode failure of any one relay would cause a system closed-mode failure, and an open-mode failure of all *n* relays would cause an open-mode failure of the system. Therefore, adding components to the system may decrease the system reliability. (The designations "closed mode" and "short mode" both appear in this chapter, and these two terms will be used interchangeably.)

System reliability where components have various failure modes is covered in [16, 17, 21–24]. This section briefly discusses the aspects of the **reliability optimization** of systems subject to two types of failure. Reliability optimization of several configurations such as parallel-series, series-parallel, and *k-out-of-n* systems subject to two types of failure will be discussed.

Consider a series system consisting of *n* components. In this series system, any one component failing in an open mode causes system failure, whereas all components of the system must malfunction in short mode for the system to fail. The reliability of series system is given by:

$$R_s(n) = (1 - q_0)^n - q_s^n \quad (19)$$

where *n* is the number of identical and independent components. For given values of q_0 and q_s , it can

be shown that there exists an optimum number of components, say n^* , that is

$$n^* = \begin{cases} \lfloor n_0 \rfloor + 1 & \text{if } n_0 \text{ is not an integer} \\ n_0 \text{ or } n_0 + 1 & \text{if } n_0 \text{ is an integer} \end{cases} \quad (20)$$

where

$$n_0 = \frac{\log\left(\frac{q_0}{1-q_s}\right)}{\log\left(\frac{q_s}{1-q_0}\right)} \quad (21)$$

that maximizes the reliability of series system.

Consider a parallel system consisting of n components. For a parallel configuration, all the components must fail in open mode or at least one component must malfunction in short mode to cause the system to fail completely. The system reliability is

$$R_p(n) = (1 - q_s)^n - q_0^n \quad (22)$$

where n is the number of components connected in parallel. Define

$$n_0 = \frac{\log\left(\frac{q_s}{1-q_0}\right)}{\log\left(\frac{q_0}{1-q_s}\right)} \quad (23)$$

For given values of q_0 and q_s , the parallel system reliability $R_p(n^*)$ is maximum for

$$n^* = \begin{cases} \lfloor n_0 \rfloor + 1 & \text{if } n_0 \text{ is not an integer} \\ n_0 \text{ or } n_0 + 1 & \text{if } n_0 \text{ is an integer} \end{cases} \quad (24)$$

Consider a system of components arranged so that there are m subsystems operating in parallel, each subsystem consisting of n i.i.d. components in a series. Such an arrangement is called a *parallel-series arrangement*. Define q_0 be the open-mode failure probability of each component ($p_0 = 1 - q_0$) and q_s the short-mode failure probability of each component ($p_s = 1 - q_s$). The system can be (a) good, (b) failed open (at least one component in each subsystem fails open), or (c) failed short (all the components in any subsystem fail short). The system reliability is given by

$$R_{ps}(n, m) = (1 - q_s^n)^m - [1 - (1 - q_0)^n]^m \quad (25)$$

Let n , q_0 , and q_s be fixed. The maximum value of $R_{ps}(m)$ is attained at $m^* = \lfloor m_0 \rfloor + 1$, where

$$m_0 = \frac{n(\log p_0 - \log q_s)}{\log(1 - q_s^n + \log(1 - p_0^n))} \quad (26)$$

If m_0 is an integer, then m_0 and $m_0 + 1$ both maximize $R_{ps}(m)$.

The series-parallel structure to be discussed is the dual of the parallel-series structure above. It is a system of components arranged in such a way that there are m subsystems operating in a series with each subsystem consisting of n i.i.d. in parallel. Such an arrangement is called a *series-parallel arrangement*. The series-parallel system reliability is given by

$$R(m) = (1 - q_0^n)^m - [1 - (1 - q_s^n)]^m \quad (27)$$

Barlow *et al.* [24] show that there exists no pair (m, n) maximizing system reliability. However, for fixed n , q_0 , and q_s , however, one can determine the value of m that maximizes the system reliability $R(m)$ where $m^* = \lfloor m_0 \rfloor + 1$, and

$$m_0 = \frac{n(\log p_s - \log q_0)}{\log(1 - q_0^n - \log(1 - p_s^n))} \quad (28)$$

If m_0 is an integer, then m_0 and $m_0 + 1$ both maximize $R(m)$.

The k -out-of- n Systems. Consider a model in which a k -out-of- n system is composed of n identical and independent components that can be either good or failed. The components are subject to two types of failure: failure in an open mode and failure in a closed mode. The system can fail when k or more components fail in a closed mode or when $(n - k + 1)$ or more components fail in an open mode. The k -out-of- n system reliability is given by

$$R(k, n) = \sum_{i=0}^{k-1} \binom{n}{i} q_s^i p_s^{n-i} - \sum_{i=0}^{k-1} \binom{n}{i} p_0^i q_0^{n-i} \quad (29)$$

For fixed k , q_0 , and q_s , the maximum value of $R(k, n)$ is attained at $n^* = \lfloor n_0 \rfloor$ where

$$n_0 = k \left[1 + \frac{\log\left(\frac{1-q_0}{q_s}\right)}{\log\left(\frac{1-q_s}{q_0}\right)} \right] \quad (30)$$

If n_0 is an integer, both n_0 and $n_0 + 1$ maximize $R(k, n)$. For any given q_0 and q_s , we can easily obtain

the following bounds for the optimal value of the threshold k : $nq_s < k^* < np_0$

This result shows that for given values of q_0 and q_s , an upper bound for the optimal threshold k^* is the expected number of components working in the open mode, and a lower bound for the optimal threshold k^* is the expected number of components failing in the closed mode.

Weighted Systems with Multiple Failure Modes.

In many applications, ranging from target detection to pattern recognition, including safety-monitoring protection, undersea communication, and human organization systems, a decision has to be made on whether or not to accept the hypothesis, based on the given information, so that the probability of making a correct decision is maximized. In safety monitoring protection systems, e.g., in a nuclear power plant, where the system state is monitored by a multichannel sensor system, various core groups of sensors monitor the status of neutron flux density, coolant temperature at the reaction core exit (outlet temperature), coolant temperature at the core entrance (inlet temperature), coolant flow rate, coolant level in pressurizer, and on-off status of coolant pumps. Hazard-preventive actions should be performed when an unsafe state is detected by the sensor system.

In undersea communication and decision-making systems, the system consists of n electronic sensors with each scanning for an underwater enemy target [25]. Some electronic sensors, however, might falsely detect a target when none is approaching. Therefore, it is important to determine a threshold level that maximizes the probability of making a correct decision. All these applications have the following working principles in common. (a) System units make individual decisions; thereafter, the system as an entity makes a decision based on the information from the system units. (b) The individual decisions of the system units need not be consistent and can even be contradictory; for any system, rules must be made on how to incorporate all information into a final decision. System units and their outputs are, in general, subject to different errors, which in turn affect the reliability of the system decision.

This section presents a brief summary of recent studies in reliability analysis of systems with three failure modes. Pham [16] studied a dynamic redundant system with three failure modes. Each unit is subject to stuck-at-0, stuck-at-1, and stuck-at- x failures. The system outcome is either good or failed.

Focusing on the dynamic majority and k -out-of- n systems, Pham derived **optimal design** policies for maximizing the system reliability. Nordmann and Pham [26] have presented a simple algorithm to evaluate the reliability of weighted dynamic-threshold voting systems, and Nordmann and Pham [18] also presented a general analytic method for evaluating the reliability of weighted-threshold voting systems. It is worth considering the reliability of weighted voting systems with time dependency.

Load-Sharing Redundant Systems

In reliability, it is common practice to use redundancy techniques to improve system reliability. In most cases, when analyzing redundancy, independence is assumed across the components within the system. In other words, it is assumed that the failure of a component does not affect the failure properties (failure rates) of the remaining components. In the real world, however, many systems are **load sharing**, where the assumption of independence is no longer valid. In a load-sharing system, if a component fails, the same workload has to be shared by the remaining components, resulting in an increased load shared by each surviving component [27]. Load-sharing models have a wide range of engineering applications. They are extensively used in the textile engineering (fibers) [28], material science and testing (fatigue and crack growth), mechanical engineering, and civil and structural engineering (welded joint on large support structures) disciplines. Further, load-sharing models have interesting applications in nuclear reactor safety [27], **software reliability** [29], and condition-based maintenance [30].

Now the author will briefly discuss the pattern of loads acting on the system, load-sharing policies that dictate how the load on the system is distributed among the components, and the relationship between the dynamic load and the failure behavior of the components over a period of time. In load-sharing systems, the components of the system are subjected to varying loads for numerous reasons, including changing demands of the system, failure of some components, changes in the operating conditions and so on. The most important element of the load-sharing model is the rule that governs how the loads on the working components change after some components in the system fail. For example:

- Equal load-sharing rule. A constant system load is distributed equally among the working components. Examples of this kind include yarn bundles and untwisted cables that spread the stresses uniformly after individual failures.
- Local load-sharing rule. A load on a failed component is transferred to adjacent components, and the proportion of the load that the surviving components inherit depends on their “distance” to the failed component. Examples of this kind include cables supporting bridges and other structures, composite materials with bounding matrix joins, and transmission systems that are modeled using consecutive k -out-of- n systems.

In load-sharing systems, it is worth to note that a component operates at different loads during different time intervals. Therefore, it is important to consider the effects of load history on the component failure rate.

HOANG PHAM

Stress–Strength Model

Introduction

Let X and Y be two continuous random variables with cumulative distribution functions $F(x)$ and $G(y)$, respectively. Let Y denote the strength of a component subject to stress X . Then the component fails if the applied stress or load is greater than its strength or resistance. The *reliability* of the component is given by

$$R_1 = P(X < Y) \quad (1)$$

The above *stress-strength model* has been useful in a number of areas, especially in the structural and aerospace industries. As an example consider the following problem. A solid propellant rocket engine is successfully fired, provided the chamber pressure (X) generated by ignition stays below the burst pressure (Y) of the rocket engine. If $X > Y$, the engine blows up and the operation is a failure. The probability of failure is

$$P_1 = 1 - R_1 = P(X > Y) \quad (2)$$

From practical considerations it is desirable to draw an inference about the reliability function R_1 . The problems of estimating R_1 have been considered by many using nonparametric, parametric, and Bayesian approach. We present a survey of some of these results.

For a bibliography of relevant literature see Basu [1–4], Basu and Ebrahimi [5], Basu and Tarmast [6], Basu and Thompson [7], Thompson and Basu [8], Sun, Ghosh and Basu [9], Johnson [10] and the references given there.

Nonparametric Approach

Let $X_1, X_2, \dots, X_m$ be a random sample of size m of stresses and $Y_1, Y_2, \dots, Y_n$ be a random sample of size n of strength. The Mann–Whitney statistic U is

$$U = \sum_{i=1}^m \sum_{j=1}^n U_{ij} \quad (3)$$

and

$$U_{ij} = \begin{cases} 1, & \text{if } X_i < Y_j \\ 0, & \text{otherwise} \end{cases} \quad (4)$$

Here, U is the number of pairs (X_i, Y_j) with $X_i < Y_j$. The point estimate

$$\hat{R}_1 = \frac{U}{mn} \quad (5)$$

was first proposed by Birnbaum [11]. $\hat{R}_1$ is the uniform minimum variance unbiased estimator of R_1 . Note that since probability of failure $P_1 = P(X > Y) = 1 - R_1 = 1 - P(X < Y)$, we can either estimate R_1 or P_1 . That is, $\hat{P}_1 = 1 - \hat{R}_1$.

Birnbaum obtained one-sided **confidence interval** for P_1 for the case where F is known, and G unknown ($m \rightarrow \infty$), and both F and G are unknown. Birnbaum and McCarty [12] considered a numerical procedure for computing the sample sizes needed for the confidence interval based on $\hat{R}_1$.

Owen *et al.* [13] showed that the assumption of continuity required in Birnbaum [11] was not essential and produced some tables for use in computing sample sizes needed and computing confidence intervals for the Birnbaum–McCarty procedure. Govindarajulu [14] has also explicitly derived one-sided and two-sided distribution-free confidence bounds for R_1 based on the asymptotic normality of

$$\hat{P}_1 = 1 - \frac{U}{mn} = \sum_{i=1}^m \sum_{j=1}^n \frac{(1 - U_{ij})}{mn} \quad (6)$$

These bounds are approximately one half of the corresponding bounds due to Birnbaum and McCarty. In particular, for all F and G and large m or n , the solution of ϵ of the equation $P(R_1 \leq \hat{R}_1 + \epsilon) = P(R_1 \geq \hat{R}_1 - \epsilon) \geq \gamma$ is $t_1 = (2r)^{-1/2} \Phi^{-1}(\gamma)$, $0 < \gamma < 1$ and the solution of ϵ of the equation $P(|\hat{R}_1 - R_1| \leq \epsilon) \geq \gamma$, $0 < \gamma < 1$, is given by $t_2 = (4r)^{-1/2} \Phi(1 + \gamma/2)$. Here $\Phi(x) = 1/\sqrt{2\pi} \int_{-\infty}^x e^{-u^2/2} du$, and $\Phi^{-1}(\cdot)$ is the inverse function of $\Phi(\cdot)$.

Johnson [10] has also given a survey of some of these results.

Parametric Approach

In many situations, the family of the distribution of X and/or Y will be known, and it is desirable to obtain parametric solutions. We consider a number of cases for estimating R_1 for specific parametric distributions.

2 Stress–Strength Model

Normal Distribution

Owen *et al.* [13], gave one-sided confidence intervals for R_1 when (a) X and Y follow a bivariate **normal distribution** and observations (X, Y) are in pairs, or (b) when X and Y are independent normal with a common unknown variance. Govindarajulu [14] obtained two-sided confidence intervals for R_1 . Basu [3] and Johnson [10] present some of these results.

Let us assume that $f(\cdot)$ is $N(\mu_1, \sigma_1^2)$ and $g(\cdot)$ is $N(\mu_2, \sigma_2^2)$. Then

$$R_1 = P(X < Y) = \Phi\left(\frac{\mu_2 - \mu_1}{\sqrt{\sigma_1^2 + \sigma_2^2}}\right) \quad (7)$$

where Φ is the standard normal **cdf**. The maximum-likelihood estimator of R_1 is

$$\hat{R}_1 = \Phi\left(\frac{\bar{Y} - \bar{X}}{\sqrt{\hat{\sigma}_1^2 + \hat{\sigma}_2^2}}\right) \quad (8)$$

Here $\bar{X} = \frac{1}{m} \sum X_i$, $\bar{Y} = \frac{1}{n} \sum Y_i$, and $\hat{\sigma}_1^2 = \sum (X_i - \bar{X})^2 / m$, $\hat{\sigma}_2^2 = \sum (Y_i - \bar{Y})^2 / n$.

For large m and n , an approximate $100(1 - \alpha)\%$ lower confidence bound for R_1 is given by

$$R_1 = \Phi\left(\frac{\bar{y} - \bar{x}}{\sqrt{\hat{\sigma}_1^2 + \hat{\sigma}_2^2}}\right) - \frac{z_\alpha \hat{\sigma}_{R_1}}{\sqrt{m + n}} \quad (9)$$

where $1 - \alpha = \Phi(z_\alpha)$.

In the special case of equal variances, $\sigma_1^2 = \sigma_2^2$, the lower confidence bound on R_1 is given by Johnson [10].

Exponential Distribution

Since in many physical situations, especially in reliability and life testing problems the exponential distribution is considered a more realistic model, we shall consider estimating R_1 when X and Y follow independent exponential distributions with density functions

$$f(x) = \frac{1}{\theta_1} e^{-x/\theta_1}, \quad x > 0, \quad \theta_1 > 0 \quad (10)$$

and

$$g(y) = \frac{1}{\theta_2} e^{-y/\theta_2}, \quad y > 0, \quad \theta_2 > 0 \quad (11)$$

respectively. Here

$$R_1 = P(X < Y) = \frac{\theta_2}{\theta_1 + \theta_2} \quad (12)$$

Given two independent samples $(X_1, X_2, \dots, X_m)$ and $(Y_1, Y_2, \dots, Y_n)$ from $f(\cdot)$ and $g(\cdot)$, respectively, the maximum-likelihood estimator of R_1 is given by

$$\hat{R}_1 = \frac{\bar{Y}}{(\bar{X} + \bar{Y})} = \frac{1}{(\bar{X}/\bar{Y} + 1)} \quad (13)$$

Since $\hat{R}_1$ is a function of $\bar{X}/\bar{Y}$, the exact distribution of $\hat{R}_1$ can be obtained. Note $(\bar{X}\theta_2)/(\bar{Y}\theta_1)$ follows the F distribution with $(2m, 2n)$ **degrees of freedom**, a $100(1 - \alpha)\%$ lower confidence bound on R_1 is given by

$$\frac{1}{\left(1 + \frac{\bar{X}}{\bar{Y}} F_{2n, 2m}^{(\alpha)}\right)} < R_1 \quad (14)$$

where $F_{2n, 2m}^{(\alpha)}$ is the upper α th point of the $F_{2n, 2m}$ distribution.

Basu [3] has also considered the cases where the underlying distributions are (a) γ with known shape parameters, (b) Weibull with known common shape parameter, and (c) the case where (X, Y) follow the bivariate exponential distribution of Marshall and Olkin [15].

Bayesian Analysis of Complex Systems

Enis and Geisser [16] and Johnson [10] have considered the Bayesian inference for R_1 where the underlying distributions are normal. We shall here primarily consider the case when X and Y follow independent exponential distributions. The conditional density functions, conditional on the parameters θ_1 and θ_2 , are

$$f(x|\theta_1) = \frac{1}{\theta_1} \exp(-x/\theta_1) \quad (15)$$

and

$$g(y|\theta_2) = \frac{1}{\theta_2} \exp(-y/\theta_2) \quad (16)$$

for $(x, y, \theta_1, \theta_2 > 0)$. Then

$$\begin{aligned} R_1(\theta_1, \theta_2) &= P(X < Y | \theta_1, \theta_2) \\ &= \theta_2 / (\theta_1 + \theta_2) \\ &= \left(\frac{\lambda}{1 + \lambda} \right) \end{aligned} \quad (17)$$

where $\lambda = \theta_2 / \theta_1$. We assume that the parameters θ_1 and θ_2 are independently distributed. Then the prior density of θ_1 and θ_2 is $p(\theta_1, \theta_2) = p_1(\theta_1)p_2(\theta_2)$ where $p_i(\cdot)$ is prior density of θ_i , $i = 1, 2$. Given independent random samples $X_1, X_2, \dots, X_m$ and $Y_1, Y_2, \dots, Y_n$ form $f(\cdot | \theta_1)$ and $g(\cdot | \theta_2)$, we can obtain the posterior distribution of (θ_1, θ_2) , R_1 , and λ as given by Basu and Ebrahimi [5]. We shall now consider Bayesian estimates of reliability for complex systems.

k-out-of-p Systems

Let us consider a *k-out-of-p* system where a system has p components and the system functions if and only if at least k of these p components function successfully. When $k = p$ (or $k = 1$) we obtain a series (or parallel) system. If $k = p = 1$, the system is as described in the section titled “Introduction”. Basu and Tarmast [6] describe such systems. First, let us consider a system of strength Y which is subjected to p different stresses $X_1, X_2, \dots, X_p$. An example of interest is the case where a beam of strength Y is subjected to p different stresses. We assume X_i ’s and Y are independently distributed where the common conditional density of X_i ’s is exponential $f(\cdot | \theta_1)$ and Y also follows the exponential distribution with conditional density $g(\cdot | \theta_2)$. Basu and Tarmast [6] show that the system reliability is

$$\begin{aligned} R_2 &= P(\text{at least } k \text{ of the } X_i \text{'s} < Y) \\ &= \frac{\Gamma(p+1)\Gamma\left(p + \frac{1}{\lambda} + 1 - k\right)}{\left\{ \Gamma(p+1-k)\Gamma\left(p + \frac{1}{\lambda} + 1\right) \right\}} \end{aligned} \quad (18)$$

Next consider a p -component system with strengths $Y_1, Y_2, \dots, Y_p$ respectively, and each component is subjected to the same stress X . Here X and Y_i ’s follow independent exponential distributions with $X \sim f(\cdot | \theta_1)$ and $Y_i \sim g(\cdot | \theta_2)$. Then the system reliability

is given by

$$R_3 = 1 - \frac{\Gamma(k+\lambda)\Gamma(p+1)}{\Gamma(p+\lambda+1)\Gamma(k)} \quad (19)$$

Finally, consider a more general p -component system where the i th component of strength Y_i is subject to stress (shock) X_i , $i = 1, 2, \dots, p$. Assuming that the X_i ’s and Y_i ’s are independent exponential distributions with conditional densities of X_i and Y_i are $f(\cdot | \theta_1)$ and $g(\cdot | \theta_2)$, respectively.

Then the reliability of the k -out-of- p system is given by

$$R_4 = \sum_{j=k}^p \binom{p}{j} \frac{\lambda^j}{(1+\lambda)^p} \quad (20)$$

Note R_1 is a special case of R_2 , R_3 , and R_4 when $p = k = 1$. Here

$$R_1 = P(X < Y) = R_2 = R_3 = R_4 = \frac{\lambda}{1 + \lambda} \quad (21)$$

Bayesian Estimation Using Noninformative Priors

Let us assume that X and Y follow independent exponential distributions. A reasonable noninformative prior distribution for θ_i is given by

$$h(\theta_i) = \frac{1}{\theta_i}, \theta_i > 0 (i = 1, 2) \quad (22)$$

Basu and Tarmast [6] obtain the following Bayesian estimates for R_2 , R_3 , and R_4 .

$$\begin{aligned} \hat{R}_2 &= \frac{\Gamma(m+n)\Gamma(p+1)}{\Gamma(m)\Gamma(n)\Gamma(p+1-k)} \\ &\times \int_0^1 \left(\frac{p+1+k+\frac{1-y}{uy}}{\Gamma\left(p+1+\frac{1-y}{uy}\right)} \right) y^{m-1}(1-y)^{n-1} dy \end{aligned} \quad (23)$$

$$\begin{aligned} \hat{R}_3 &= 1 - \frac{\Gamma(m+n)\Gamma(p+1)}{\Gamma(m)\Gamma(n)\Gamma(k)} \\ &\times \int_0^1 \frac{\Gamma\left(k+\frac{uy}{1-y}\right) y^{m-1}(1-y)^{n-1}}{\Gamma\left(p+1+\frac{uy}{1-y}\right)} dy \end{aligned} \quad (24)$$

and

$$\hat{R}_4 = \sum_{j=\kappa}^p \binom{p}{j} \frac{\Gamma(m+n)u^j}{\Gamma(m)\Gamma(n)} \times \int_0^1 \frac{y^{m+j-1}(1-y)^{n-p-j-1}}{(1+(u-1)y)^p} dy \quad (25)$$

Here $u = (n\bar{y}/m\bar{x})$.

Basu and Ebrahimi [5] and Basu and Tarmast [6] have also considered Bayesian estimates of R_i ($i = 1, 2, 3, 4$) when the θ_i 's have independent conjugate **prior distributions**. Sun *et al.* [9] have considered Bayesian estimation of R_1 using noninformative priors. Basu and Thompson [7] Thompson and Basu [8] also derived the posterior densities of the reliabilities of exponential stress-strength systems using subjective and noninformative priors.

Reliability Optimization

Introduction

A reliability engineer's job is to make systems (hardware, software, human) as reliable as possible. In this article, we look at how systems can be made as reliable as possible, under the constraints that are imposed. We consider three approaches to reliability optimization.

1. Optimize the reliability of the components that make up the system. This can be done through the use of experimental design to find the parameters of the design or the parameters of the process that produce the components.
2. Redundancy can be used to increase system reliability (*see Reliability of Redundant Systems; Parallel, Series, and Series-Parallel Systems*).
3. Preventive maintenance can be done to extend the lifetimes of key components.

These three areas are the topics of the next sections. Other approaches to optimizing reliability can be found in Kuo *et al.* [1].

Optimizing Component Reliability

Meeker and Hamada [2] provide an overview of strategies for optimizing **component reliability**, including

1. life testing
2. **degradation** testing
3. designed experiments
4. monitoring field and warranty data.

We will focus on the use of designed experiments for achieving component reliability. Experimental design has been used for quite a while to choose the parameters of a product or process that optimize the resulting quality. See Box *et al.* [3] and Montgomery [4]. Until recently, most work has been done under the assumption that the output is a normally distributed random variable. One problem with applying these methods in reliability is that the output of a life test is a lifetime, and the normal distribution is usually a poor model for lifetimes. Another potential problem is the presence of censoring, that is the termination

of a life test before all units have failed. Hamada [5] describes likelihood-based methods for experiments in which the output is a lifetime and censoring is possible. Depending on the amount of censoring, the maximum-likelihood estimates of the factor effects might not exist. Hamada and Wu [6] present a Bayesian approach, for which factor effects always exist.

One example discussed in both Hamada [5] and Hamada and Wu [6], originally due to Taguchi [7], involves the lifetimes of a fluorescent lamp. The experiment involved five factors, which we will call A , B , C , D , and E . Each factor had two levels, denoted by “−” and “+”. Two lamps were made at each of eight different treatments (i.e., combinations of factors). The experimental design was a one-fourth replication of a 2^5 **factorial** design, denoted 2^{5-2} . These eight runs were chosen in such a way that all combinations of three variables gives a full 2^3 factorial design. The fourth and fifth variables, called D and E , are set according to the defining relationships $D = -AC$ and $E = -BC$. Under this assignment, the 2^{5-2} design has resolution III, meaning that main effects are confounded with two-factor interactions. The lamps were inspected periodically, so the exact lifetimes were unknown. Since all that was observed was that a light was burning at one time, t_1 , and not at the next inspection time, t_2 , it was known only that the failure occurred in the interval (t_1, t_2) . This is a special type of censoring called *interval censoring*. The last inspection was done at time 20, and 7 of the 16 lamps were still burning at this time. This is the usual situation of type I censoring. From the analyses in Hamada [5] and Hamada and Wu [6], the authors concluded that the significant factors, in order of significance, were D , B , E , and A . With this knowledge, it was possible to alter the process or product design so as to maximize the lifetime of the lamp.

Reliability Allocation

It may be possible to increase component reliabilities, but at a cost. Suppose we have an n -component system with component reliabilities, denoted $\mathbf{r} = (r_1, r_2, \dots, r_n)$. The system reliability is then a function of $\mathbf{r}$,

$$R_s = f(r_1, r_2, \dots, r_n) = f(\mathbf{r}) \quad (1)$$

Achieving a reliability of r_j for component j involves a cost $g(r_j)$. There are constraints on the total cost

2 Reliability Optimization

(B) and there may be lower and upper bounds (l_j and u_j) on each component's reliability. The constrained optimization problem is therefore

$$\begin{aligned} \text{Maximize : } & R_s = f(r_1, r_2, \dots, r_n) \\ \text{Subject to : } & \sum_{j=1}^n g_j(r_j) \leq B \\ & l_j \leq r_j \leq u_j, \quad j = 1, 2, \dots, n \end{aligned}$$

For example, consider an n -component series system with equal component reliabilities, for which

$$R_s = f(r_1, r_2, \dots, r_n) = r^n \quad (2)$$

Suppose that the reliability cost function for each system is

$$g_j(r_j) = \frac{1}{1 - r_j} \quad (3)$$

The total cost is therefore

$$\sum_{j=1}^n \frac{1}{1 - r_j} = \frac{n}{1 - r} \quad (4)$$

For this cost function, the cost goes to infinity as the reliability approaches 1 from the left; in other words, it becomes more and more expensive to increase reliability as the reliability gets close to 1. The optimization problem then becomes

$$\begin{aligned} \text{Maximize : } & r^n \\ \text{Subject to : } & \frac{n}{1 - r} \leq B \\ & 0 \leq r_j \leq 1, \quad j = 1, 2, \dots, n \end{aligned}$$

The solution to this problem is to take r to be as large as possible, while maintaining the constraint $n/(1 - r) \leq B$, that is $r = 1 - n/B$.

For a nontrivial example, consider the three-component system shown in Figure 1, where components 1a and 1b have identical reliability, r_1 , and component 2 has reliability r_2 .

Figure 1 Structure diagram for series-parallel system

Figure 2 System reliability R_s as a function of r_1

The optimization problem becomes

$$\begin{aligned} \text{Maximize : } & [1 - (1 - r_1)^2] r_2 \\ \text{Subject to : } & \frac{1}{1 - r_1} + \frac{1}{1 - r_2} \leq B \\ & 0 \leq r_j \leq 1, \quad j = 1, 2 \end{aligned}$$

The highest reliability will be attained when the total cost is B , in which case

$$r_2 = \frac{B - 2 - (1 - B)r_1}{1 - B - Br_1} \quad (5)$$

Thus,

$$R_s = [1 - (1 - r_1)^2] \frac{B - 2 - (1 - B)r_1}{1 - B - Br_1} \quad (6)$$

a function of a single variable. Figure 2 shows R_s as a function of r_1 . A numerical procedure gave us the result that R_s attains a maximum when $r_1 = 0.956074$. For this value of r_1 , we have $r_2 = 0.987052$ giving a system reliability of $R_s = 0.985148$.

Only in special cases will we be able to reduce the problem to solving a single equation. Usually we will be left with a nonlinear constrained optimization problem.

Redundancy Allocation

Each component can be backed up by a number of redundant components. Let x_j denote the number of redundant parts for component j . The component

reliabilities are assumed to be fixed. The system reliability is then a function of the number of redundant parts for each component. For example, suppose the system is an n -component series system, having reliability $R_s = r_1 r_2 \cdots r_n$ if there is no redundancy. If component j has x_j redundant parts then the system is a series-parallel system, as shown for illustration in Figure 3 for $n = 4$, $x_1 = 2$, $x_2 = 1$, $x_3 = 2$, and $x_4 = 3$. With redundancy, the system reliability is

$$R_s = \prod_{j=1}^n \left[1 - (1 - r_j)^{x_j+1} \right] \quad (7)$$

Let $g_j(x_j)$ denote the cost of having x_j redundant parts for component j . There may be constraints on the number of redundant parts, for example physical size and space may pose a limit. The optimization problem is therefore

$$\text{Maximize : } R_s = \prod_{j=1}^n \left[1 - (1 - r_j)^{x_j+1} \right]$$

$$\text{Subject to : } \sum_{j=1}^n g_j(x_j) \leq B$$

$$L_j \leq x_j \leq U_j, \quad j = 1, 2, \dots, n$$

This is a nonlinear integer programming problem, because the variables x_j are necessarily integers.

For example, consider a three-component series system. Suppose that the cost functions are

$$g_j(x_j) = (x_j + 1)C_j \quad (8)$$

indicating that the cost is proportional to the number of components (operating and redundant), where $C_1 = 1$, $C_2 = 2$, and $C_3 = 3$. Suppose also that the component reliabilities are $r_1 = r_2 = 0.95$ and

$r_3 = 0.99$, and that the cost constraint is $B = 12$. The corresponding system reliabilities and costs are shown in Table 1 for a number of combinations of (x_1, x_2, x_3) . The entries below the line violate the constraint that the cost must not exceed 12. Among all the combinations whose cost does not exceed 12, the one with the highest reliability is $(x_1, x_2, x_3) = (2, 2, 0)$, giving a system reliability of 0.9898 and a cost of $B = 12$. Thus the optimum is to have the original and two spares for components 1 and 2, and to have the original and no spares for component 3. This makes intuitive sense, because component 3 already has the highest component reliability.

With only three components, the possibilities can be enumerated in a table like the one shown in Table 1. For larger problems, methods of nonlinear integer programming must be used to find the optimum redundancy.

Reliability and Redundancy Allocation

Suppose now that there are costs associated with increasing reliability and adding redundancy. Following the notation of the previous sections, we define

r_j := reliability of component j and

x_j := number of redundant parts for component j

Let $g_j(r_j, x_j)$ be the cost of achieving reliability r_j for each copy of component j , while having x_j redundant parts. We would then pose our optimization problem as follows:

$$\text{Maximize : } R_s = f(r_1, r_2, \dots, r_n)$$

$$\text{Subject to : } \sum_{j=1}^n g_j(r_j, x_j) \leq B$$

Figure 3 Structure diagram for series system with redundancy

3	0	3	0.95	18	3	1	3	0.9975	20	3	2	3	0.99987	22	3	3	3	0.99999	24

$$l_j \leq r_j \leq u_j, \quad j = 1, 2, \dots, n$$

$$L_j \leq x_j \leq U_j, \quad j = 1, 2, \dots, n$$

This is a nonlinear mixed integer programming problem. See Kuo *et al.* [1] for methods of solving such optimization problems.

Optimal Maintenance

For a repairable system, the question is often when to replace or overhaul an old system. Replacing (or renewing) the system too often is expensive, but an old deteriorating system may fail often, requiring many repairs. The objective is to choose the time between renewals to minimize the cost. There are many possible cost models for this scenario, but we discuss just a very simple one. Suppose that the failure process is a power law process (*see Repairable Systems: Statistical Inference*) with parameters β and θ . We assume that $\beta > 1$, otherwise the system is improving and it would never be optimal to replace an improving system. Let A denote the cost of replacing an old system with a brand-new one, and let B denote the cost of a repair. Some cost models impose a distribution on the value of B , but we will assume that it is a constant. If we consider the time interval $[0, T]$, where T is large, then the number of replacements will be $\lfloor T/a \rfloor$, occurring at times $a, 2a, 3a, \dots, \lfloor T/a \rfloor a$.

Over the interval $[(k-1)a, ka]$, $k = 1, 2, \dots, \lfloor T/a \rfloor$, there will be N_k failures/repairs, where

N_k has a Poisson distribution with mean $(a/\theta)^\beta$. (Since the times between replacements are constant and nonoverlapping, the N_k are independent and identically distributed (i.i.d.)) The number of failures between the last replacement at time $\lfloor T/a \rfloor a$ and time T has a Poisson distribution with mean $((T - \lfloor T/a \rfloor a)/\theta)^\beta$. The expected cost over the interval $[0, T]$ for the strategy of replacing the system every a time units is

$$C_T(a) = E(\text{Cost}[0, T]) = \left\lfloor \frac{T}{a} \right\rfloor A + \left\lfloor \frac{T}{a} \right\rfloor E(N_1) B + E(\text{number of failures in } [\lfloor T/a \rfloor a, T]) B \quad (9)$$

The long-run average cost is obtained by dividing by T and taking the limit as $T \rightarrow \infty$,

$$\begin{aligned} C_\infty(a) &= \lim_{T \rightarrow \infty} \frac{E(\text{Cost}[0, T])}{T} \\ &= \lim_{T \rightarrow \infty} \left\lfloor \frac{T}{a} \right\rfloor \frac{A}{T} + \lim_{T \rightarrow \infty} \left\lfloor \frac{T}{a} \right\rfloor \frac{B}{T} \left(\frac{a}{\theta} \right)^\beta \\ &\quad + \lim_{T \rightarrow \infty} E(\text{number of failures in } [\lfloor T/a \rfloor a, T]) \frac{B}{T} \\ &= \frac{A}{a} + \frac{B}{a} \left(\frac{a}{\theta} \right)^\beta = Aa^{-1} + \frac{B}{\theta^\beta} a^{\beta-1} \end{aligned} \quad (10)$$

Figure 4 Cost functions $C_{\infty}(a)$ for $\beta = 1.5$ and $\beta = 2$

The minimum cost can be obtained by setting $C'_{\infty}(a) = 0$ and solving for a . This yields

$$a = \theta \left(\frac{A}{B(\beta - 1)} \right)^{1/\beta} \quad (11)$$

Figure 4 shows the cost functions $C_{\infty}(a)$ for $A = 100$, $B = 1$, $\theta = 1$ (i.e. the cost of replacement is 100 times the cost of a repair) and for two different values of β , namely $\beta = 1.5$ and $\beta = 2$. The optimal replacement times are

$$a = 1 \left(\frac{100}{1 \times (1.5 - 1)} \right)^{1/1.5} \approx 34.2 \quad (12)$$

and

$$a = 1 \left(\frac{100}{1 \times (2 - 1)} \right)^{1/2} = 10 \quad (13)$$

Figure 4 indicates that when $\beta = 1.5$ the optimal time between replacements is larger than when $\beta = 2$. This should be expected, because the system is deteriorating faster when $\beta = 2$, so more frequent replacements would be called for.

There are numerous other models for preventive maintenance. See, for example, Wang and Pham [8] and Blischke and Murthy [9].

Reliability Databases

Introduction

Reliability data consists of information relating to the performance of an item, or a collection of related items (referred to here as *systems*), such as the number of on-demand or time-dependent failures, the length of time taken to repair an item or the operating time between failures. A *reliability data bank* is an organized collection of processed reliability data based on the available raw data. The available raw data is the information that can be extracted from the primary sources. The nature of the primary sources will depend on the specific application, but commonly occurring primary data sources include records of maintenance work requests, measures of system output, and details of necessary repair work.

Recording system output and maintenance allows system owners to monitor performance. The objective of performance monitoring is to learn about the system with a view to predicting future system behavior. The system owner is concerned about the efficient operation of the system, and by improving his understanding of the frequency, and the causes, of system failure, he can act to improve operational efficiency in an informed way. The gathering of reliability data is a necessary step in learning about system performance. The reliability data bank contains the primary data, processed in such a way that the link to the raw data is clear [1].

Reliability databases (RDBs) are defined by Fragola [1], to be:

“A pre-selected, processed output produced and usually available in hard copy form designed to be useful for a variety of analyses whose general type and depths have been anticipated by the database design specification.”

This definition makes clear the dependence of the database on the analyses for which it is intended. There is, therefore, a requirement to consider the different aims of different users when designing an RDB. Cooke and Bedford [2] identify three groups of users of RDBs, and their different aims:

- maintenance engineers interested in measuring and optimizing maintenance performance;
- component designers interested in optimizing component performance;

- risk/reliability analysts wishing to predict reliability of complex systems.

The different aims of these users suggest they are likely to require different types of reliability data. The designer of the RDB should consider these different aims when formatting the database.

Published records of systematically collected reliability data date from 1959 with the *Martin Titan Handbook*. This contained generic failure rates for a large number of electronic components. Other notable early publications include *MIL-Handbook-217*, the *Failure Rate Data Bank*, and the *RADC Non-Electronic Reliability Notebook*. Fragola [1] provides an historical review of the evolution of RDBs. Since the 1980s, there have been attempts to standardize the methods of collecting and organizing raw data. This has resulted in a number of different standards being produced, particularly in relation to data gathering and exchange within the nuclear power industry (ISO6257, ISO7385).

There are a number of well-known RDBs currently in use. The GIDEP (Government-Industry Data Exchange Programme) data bank (maintained by the US military) contains information on the failure rate, failure mode, and replacement rate of items, systems, and subsystems based on field data, and test data. The Center for Chemical Process Safety/American Institute of Chemical Engineers (CCPS/AIChE) process equipment RDB contains reliability data relevant to the chemical and hydrocarbon processing industries. OREDA (Offshore RELiability DATA) is an organization sponsored by nine oil and gas companies that has compiled a data bank of reliability and maintenance data for offshore production equipment. The OREDA model has been accepted as an international standard (ISO14224) for database management in the offshore production industry.

The aforementioned databases contain generic data. This means the data is gathered about items used in a range of different systems and under different operating profiles. These data are then pooled, based on the specification of a range of engineering characteristics that allow the database designer to identify the data as similar in terms of, for example, physical design specification and operating conditions. These data pools may be treated as exchangeable data in some databases, enabling the use of Bayesian updating, but one should be wary of this owing to the fact that the updating

process will narrow the uncertainty range so that it no longer reflects the full range of behaviors seen within the pool. This provides average performance values, which are generally presented in terms of an expected failure rate with upper and lower bounds. RDBs can also be system-specific. System-specific databases concentrate on the failures occurring within a known system. System-specific RDBs should be subject to the same careful design as generic databases to ensure ease of interpretability in the data, although the data for system-specific databases are likely to exhibit greater homogeneity than would be expected in generic databases, thereby reducing the problems posed by grouping the data.

Taxonomies

Taxonomies provide an orderly classification of failure data. Taxonomies should be developed that use device attributes to meaningfully distinguish between the failure behavior of devices and allow investigation of the relationships between devices and their failure modes. For any given RDB, this will depend on the devices under consideration, the systems in which they are used, and the intended use of the database. However, general guidelines can be given on the development of failure and maintenance taxonomies.

Maintenance Taxonomy

Maintenance activities can be classified as either preventive maintenance (PM) or corrective maintenance (CM), which can be scheduled in different ways: calendar based, condition based, opportunity based, and emergency. **Maintenance policies** should be clearly defined, as the choice of policy influences the analysis of the failure data. PM leads to more censored data being recorded, whereas CM methods allow failure modes to be observed.

Preventive maintenance is defined as jobs that do not repair a fault or failure, but are part of regular servicing.

Corrective maintenance is defined as jobs to repair a defect, fault, or failure.

The scheduling types are as follows:

- Calendar based: planned maintenance, not based on observed **degradation**, but scheduled from

some measure of time. This scheduling type applies to PM, and does not involve repair work.

- Condition based: the component's state is observed to deviate from the manufacturer's intended state, but component functionality (as far as is required by the system) is maintained. Therefore, the component can be left until a more suitable maintenance opportunity arises. This form of scheduling involves CM.
- Opportunity based: maintenance is performed when a suitable opportunity occurs. For example, if the system has to be shut down for repairs to certain components, other components can also be maintained. There is an overlap between the concepts of condition-based and opportunity-based maintenance.
- Emergency: actions taken to repair a component that has lost functionality to the extent that the system is disabled. The system cannot function until the component has been repaired and postponing the repair is not feasible. The goal of other maintenance types is to prevent emergency action having to be taken.

Maintenance scheduling can influence the choice of maintenance actions.

Failure Taxonomy

Failure types can be classified as

- Degraded failure: the component is no longer in the state intended by the manufacturer, but is still fulfilling its system function. The component is in a noncritical degraded state.
- Critical failure: the component has ceased to function owing to critical degradation. A critically degraded component is repaired or renewed.
- Entrained functional unavailability: the component loses functionality owing to the failure of a supporting system. Repair is not necessarily required.
- Total failure: the component fails to meet its specifications to any degree.
- Nontotal critical failure: the component ceases to fulfill its function, but retains some residual functionality.

Operating Modes and Failure Mechanisms

The following three operating modes are generally considered:

- Continuous operation: the component is operating when the system is operating.
- Standby: the component is called to function on demand. Otherwise, it remains dormant.
- Alternating: the component rotates sojourns of continuous operation with one or more spares.

The alternating mode describes situations in which the components share workload according to a planned schedule, whereas standby components are generally used when the primary component can no longer function.

The operating mode of the component leads to a classification of component failures. Failures are commonly described as time related or demand related. Demand-related failures occur at the point of a component being called into service (from, for example, having been on standby). Failures occurring during continuous operation are defined to be time related. A component can have more than one operating mode, and can therefore be susceptible to both demand- and time-related failures.

Failure descriptions can be broken down into failure modes, failure mechanisms, and failure causes. Failure causes describe the reason a component fails in terms of flaws within the component, such as cracks or leaks. A failure mechanism is the physical process that leads to the failure cause. Classifying a fault as a failure cause or failure mechanism will often be a subjective process. The failure mode describes the way in which the component has failed, generally in terms of functionality. It is important to specify the failure when the failure consequences depend on how the component fails.

Structure of a Reliability Database

Example 1 A number of databases have been developed over a range of industries with the aim of providing a generic data source for common components. Fleming and Lydell [3] discuss the development of one such RDB – the PIPExp database, which is a source of pipe work reliability data, with a particular emphasis on piping used within nuclear power plants.

The development of this database was in direct response to an absence of collated reliability data on piping. Many RDBs focus on “active” components such as pumps and valves, but large parts of many industrial systems consist of “passive” components, such as piping. However, prior to 1990, most reliability studies related to piping were conducted for a specific application, and efforts were not made to exchange data, or to standardize **data collection** procedures.

Defining failure modes for passive components, such as piping, can be difficult. This is because piping failures are, in general, incipient failures, which result in loss of performance rather than loss of function. It is rare that a pipe suddenly loses structural integrity. The PIPExp database defines the failure modes as shown in Table 1.

These failure modes have been derived from the data validation and verification process to which the raw data has been subjected. The raw data for the PIPExp database consisted of a variety of source material, such as work order systems, regulatory reports, and data reconciliation with existing piping RDBs. The data has been taken from 1970 to the present. The data consists of records of 1750

Table 1 Failure modes within the PIPExp database

Failure mode	Description
Partly cracked	Crack with depth > 10% of wall thickness
Fully cracked	Through crack, but with no leakage
Wall thinning	Internal damage owing to cavitation/erosion
Small leak	Leak rate within a specified acceptable limit
Pinhole leak	As for small leak, but with different underlying damage mechanisms
Large leak	Leak rate exceeds specified limit, but can be safely managed
Severance	Full circumferential crack
Rupture	Large leak rate and major, sudden loss of structural integrity. Generally caused by a combination of internal degradation and overload

4 Reliability Databases

incidents spread over 22 million operating years. This data also allowed the identification of the following degradation mechanisms:

Corrosion
 Thermal fatigue
 Erosion cavitation
 Corrosion fatigue
 Erosion corrosion

 Stress corrosion cracking
 Vibrational fatigue
 Design dynamic loading
 Design and constructional defects

 Water hammer
 Over pressurization/overloading
 Human error
 Unreported/unknown

Point estimates for the frequency of pipe failure are given by the expression:

$$\lambda_{ijk} = \frac{n_{ijk}}{f_{ijk} N_{ij} T_{ij}} \quad (1)$$

where i is the pipe size index, j is the system index and k refers to the degradation mechanism, so n_{ijk} is the number of failure events for pipe size i in system j subject to degradation mechanism k , f_{ijk} is the fraction of components of size i in system j susceptible to degradation mechanism k , N_{ij} is the number of components belonging to the i, j subset and T_{ij} is the total operating time for those components. These estimates are presented with 5% and 95% confidence bounds, to illustrate the uncertainty estimates.

The analysis of the data is based on a Bayesian model using a Poisson likelihood for the number of observed events, and a “semi-informative” lognormal prior on λ_{ijk} . The stated confidence bounds are estimated from simulated realizations of the posterior distribution.

Analysis of RDB Data

Many different methods have been applied to the analysis of reliability data. A selection of these methods is presented here. The role of analysis is frequently to convert the available raw data into information used within other system or maintenance models. The method of analysis is determined by the

component’s failure behavior. The methods apply to the situation in which a component enters service and remains in service until it fails, with no other terminations in service.

Demand-Related Failures

Demand-related failures can be separated into *degradable* and *nondegradable* categories. A *degradable demand-related failure* is one in which the component is subject to degradation while in the standby state. Causes of degradation such as corrosion or oxidation occur, to some extent, irrespective of the operating mode of a component. Therefore, the analysis should consider this degradation.

Nondegradable demand-related failures, in which the component is considered not to have degraded over time can be modeled using a binomial distribution, in which each demand is considered to be single trial. The probability of failure per demand, p , is assumed to be independent and identical for each demand. Thus, the probability of observing f failures in d demands is given by

$$\begin{aligned} &\Pr(f \text{ failures in } d \text{ demands} | p) \\ &= \binom{d}{f} p^f (1 - p)^{d-f} \end{aligned} \quad (2)$$

The **maximum-likelihood estimation** (MLE) of p , given f failures in d demands is f/d , and the 90% confidence bounds are given by

p_l = largest p such that $\Pr(f \text{ or more failures in } d \text{ demands} | p) \leq 0.05$;
 p_u = least p such that $\Pr(f \text{ or fewer failures in } d \text{ demands} | p) \leq 0.05$.

For the *degradable* case, components are subject to maintenance. Consequently, knowledge of the maintenance procedures is required to determine reliability parameters from the data. This is illustrated using two common maintenance policies.

Under the *test and replace* policy, components are tested at a regular interval, I , and are replaced if they are found to have failed. Given uniform demand, the probability of failure on demand is given by

$$1 - \frac{1 - \exp(-\lambda I)}{\lambda I} \approx \frac{\lambda I}{2} \quad \text{for } \lambda I < 0.1 \quad (3)$$

The *fail and fix* policy allows components to fail and then performs repairs offline. During repair the

component is regarded as unavailable and therefore, any demands received would result in a demand failure. For components with a constant demand rate λ and repair rate μ , the equilibrium unavailability is given by $\frac{\lambda}{\lambda+\mu}$.

Time-Related Failures

Time-related failures are commonly modeled using exponential distributions. That is, the failure time of a component i , denoted by x_i , will have **cdf** $F(x) = 1 - \exp(-\lambda x)$. Given failure data from a collection of components, $x_1, \dots, x_n$, the MLE of λ is given by

$$\hat{\lambda} = \frac{n}{\sum_{i=1}^n x_i} \quad (4)$$

Confidence bounds for this estimate can be found by noting that $z = 2\lambda \cdot \sum_i x_i$ has a χ^2 distribution with $2n$ **degrees of freedom**. For these failures, the 90% confidence bounds are given by

$$\begin{aligned} \lambda_l &= \text{largest } \lambda \text{ such that } \Pr(\text{less than } \sum_i x_i | \lambda) \leq 5\% \\ \lambda_u &= \text{least } \lambda \text{ such that } \Pr(\text{more than } \sum_i x_i | \lambda) \leq 5\% \end{aligned}$$

If we consider a single component, with constant failure rate λ , the number of failures in given time, t , is a **Poisson process** with parameter λ and expected value λt . The MLE for λ is given by n/t .

Bayesian Models

Bayesian methods allow for the combining of different data types *via* hierarchical modeling. The imposition of a hierarchical structure allows more complex relationships to be taken into consideration, and in particular, offers a natural framework for modeling plant-specific and component-specific effects, thereby allowing data from both generic and plant-specific sources to be used in modeling.

A simple example of a one-stage Bayesian model is the Poisson–Gamma model for the rate of failure. The pattern of failures is assumed to follow a Poisson process with intensity λ . The intensity is given by the rate of occurrence of failures (ROCOF), and is itself a random quantity. We model λ as a Gamma distribution with parameters α and β , $\text{Ga}(\lambda|\alpha, \beta)$, the natural conjugate prior for Poisson variables.

If we then observe x failures in time T , our posterior for λ will be given by:

$$\begin{aligned} \Pr(\lambda|x, T) &\propto L(x, T|\lambda) \cdot \Pr(\lambda) \\ &\propto \text{Ga}(\lambda|\alpha + x, \beta + T) \end{aligned} \quad (5)$$

If the pattern of failures does follow a Poisson process with intensity $\tilde{\lambda}$, then $x/T \rightarrow \tilde{\lambda}$ as $T \rightarrow \infty$. Furthermore, our estimate is consistent.

Competing Risks

Competing-risk models are constructed by modeling each of the potential failure modes. The different failure modes are interpreted as competing to cause component failure. Assume we have k risks competing to cause component failure. These will be associated with lifetimes $X_1, \dots, X_k$. For a given realization of these variables, the value $\min\{x_1, \dots, x_k\}$ is the point at which the component fails. For such a realization, we would observe lifetime x_j and failure cause j .

Let $X_1 = X$ and $Z = \min(X_2, \dots, X_k)$. Under this construction, we are treating $X_1 = X$ as the failure mode we wish to learn about and all other failure modes as censoring variables. The naked failure rate, $r_X(t)$, is given by:

$$r_X(t) \equiv \frac{f_X(t)}{R_X(t)} = -\frac{1}{R_X(t)} \cdot \frac{dR_X}{dt} \quad (6)$$

where $R_X = 1 - F_X = \exp\left[-\int_0^t r_X(s) ds\right]$ is the subsurvival function. The naked failure rate describes the rate we could expect to observe for X , if it was never censored by Z , i.e. the rate having eliminated all other competing risks. However, when the other risks are not eliminated, the observed failure rate for X is defined as

$$\text{obr}_X(t) = \lim_{\Delta \rightarrow 0} \left[\frac{\Pr(x_j = X, X \in (t, t + \Delta) | x_j > t)}{\Delta} \right] \quad (7)$$

which coincides with $r_X(t)$ if the risks are independent.

Bounds of the value of R_X can be found [4] by noting that

$\Pr(X \leq t, X \leq Z) \leq \Pr(X \leq t) \leq \Pr(X \wedge Z \leq t)$
 $\Leftrightarrow 1 - F_X^*(t) \geq R_X(t) \geq R_X^*(t) + R_Z^*(t)$ and both $1 - F_X^*(t)$ and $R_X^*(t) + R_Z^*(t)$ are observable quantities. The Peterson bounds give an indication of the

range of possible marginal distributions. However, there can be several different marginal distributions compatible with observable data, however much data we can observe.

There are a number of viable competing-risk models available [2]. Each of these models specify an engineering situation that is being captured in the model. Therefore, model validation for these is not statistical, but engineering based.

Working with RDBs

Example 2 We now illustrate the application of a two-stage Bayesian model to the analysis of generic reliability data. This example follows the work of Bunea *et al.* [5]. Two-stage Bayesian models differ from the one-stage model discussed previously by introducing a further level of modeling to account for the uncertainty introduced by not knowing the “true” prior parameterization. In the analysis of generic reliability data, this type of modeling allows for the aleatory uncertainty associated with different data sources to be modeled, as well as the epistemic uncertainty.

The case considered by Bunea *et al.* [5] is that of the ZEDB data, which is a German-led RDB project containing events and operating times data for components at nuclear power plants in Switzerland, Germany, and the Netherlands. A two-stage hierarchical model is adopted to model the relationship between data from different plants. Data from a specific plant, i , takes the form of events, X_i , and operating/exposure times, T_i , and is modeled using a Poisson likelihood function, parameterized by λ_i :

$$l(X_i, T_i) = \frac{(\lambda_i T_i)^{X_i}}{X_i!} \exp\{-\lambda_i T_i\}, \quad \lambda_i > 0, \quad T_i > 0 \quad (8)$$

A prior distribution is assigned to each plant. The prior determines the value of λ_i and is conditioned on the hyperparameter, Q .

Q is the quantity through which the data between plants is assimilated, and the prior distribution for all i plants is conditioned on the same Q . The underlying probabilistic assumptions are (a) each plant's λ_j and its observable data X_j is independent of every other plant's λ_i given Q , and (b) each plant's observable data X_j is independent of Q and the other plants λ_i , X_i , given λ_j .

The analysis of the ZEDB data utilizes a lognormal prior for the distribution of λ_i :

$$f(\lambda|\mu, \sigma) = \frac{1}{\sigma\lambda\sqrt{2\pi}} \exp\left\{-\frac{(\ln\lambda - \mu)^2}{2\sigma^2}\right\} \quad (9)$$

which means our hyperparameters will be μ and σ . The hyperprior used in the analysis of the ZEDB data is chosen by applying Jeffrey's rule to the parameters μ and σ , resulting in a hyperprior of the form $f(\mu, \sigma) \propto 1/\sigma^2$.

Bunea *et al.* [5] explore the effects of varying the hyperpriors and the priors for this model, concluding that choosing a prior that is not conjugate is, in this case, beneficial to the analysis, as it allows for a truncation of the credible range of the hyperparameters.

Criticisms of RDBs

RDBs have faced a number of criticisms since their use has become more widespread. As the development of RDBs has evolved, some of the flaws found in early RDBs have been corrected. However, there are also a number of problems that have been compounded during development of successive databases. The problems concern both the construction of the database and the use of the data from these sources.

A major criticism of early RDBs was the way in which data was presented. Failure rates for components were often given as point estimates, with no attempt made to quantify the uncertainty surrounding this value. When estimating the failure rate from failure data, (i.e., the number of observed failures and the number of operating hours), the value obtained is an *estimate* of the typical component performance, over which we are uncertain. Recent RDBs have aimed to provide information about this uncertainty through the inclusion of confidence bounds, giving the reader a credible region in which the failure rate could lie.

However, the use of confidence bounds, or, more precisely, the way in which the confidence bounds are calculated, has also been criticized. Confidence bounds have frequently been calculated from a χ^2 distribution based on aggregated data from inhomogeneous populations. This aggregation, or pooling, of data is often conducted with the aim of collating all available data relating to a particular device or component, but overlooks the uncertainty introduced

by the different environmental and functional conditions of the subpopulations. For example, the same design of component may be more susceptible to certain types of failure depending on how it is used. The presentation of a single failure rate does not capture this information.

Attempts have been made to tackle this problem using scaling constants, called *K-factors* or π -factors. If a component is known to be operating under certain conditions, its failure rate is rescaled by the *K-factor* associated with these conditions. While *K-factors* allow component failure rates to be adjusted for different operating conditions, they do not deal with the underlying problem of incorrectly treating the uncertainty. Indeed, the use of *K-factors* compounds the problems of pooling, as inhomogeneous data is used to calculate the base failure rate for a component. The effect of ignoring the uncertainty introduced by different operating conditions is to reduce the calculated confidence bounds. The variance associated with a quantity will decrease as the sample size increases, if we assume we are sampling repeatedly from the same distribution. Pooling data makes this assumption, so it is important to assess prior to pooling that it is not an unreasonable assumption. Historically, RDBs have not always tested this assumption.

Recent databases have attempted to tackle this problem by considering the different amounts of observed variation when pooling data, using Fisher *F*-tests to assess homogeneity of samples, and increasingly, categorizing failures by failure mode. This development allows the separation of information pertaining to time- and demand-related failures and the inclusion of data on degraded and incipient failures. Categorizing the data in this way allows for greater clarity over what is meant by the failure rate data, and offers the possibility of learning about repair rates.

Another issue with generic RDBs is their limited use in troubleshooting existing designs. This has led to some critics calling for the rejection of generic data in favor of a “physics of failure” approach.

Physics of failure concentrates on modeling the potential modes of failure in terms of the underlying physical processes that cause them – such as stress, overloading, corrosion, and so on. The argument for the physics of failure approach is the limited relevance of generic data to systems operating under different conditions to those considered previously, and that physics of failure provides an approach in which the potential causes of failure are easier to identify, making appropriate maintenance easier to schedule. However, the use of generic data does allow for identification of potential failure modes, not accounted for, under physics of failure approaches. As the RDBs contain observed data, the failure modes they record include a range of “freak” failures that may not have been considered using the physics of failure approach. For this reason, the use of generic data sources and physics of failure methods can be viewed as complementary.

Fault Trees

Introduction

Fault trees are concerned with the representation of *failures*. As the name suggests, a tree structure is formed to describe the failures or faults for a system, from which analysis is carried out. The concept of the fault tree analysis (FTA) technique was developed back in 1961 by H. Watson at the Bell Telephone Laboratories. The analysis method, known as *kinetic tree theory*, was developed in 1970 by Vesely [1] and forms the basis of the technique still in use today. The method provides a visual description of the various causes of a specified system failure in terms of the failure of its components. Many different fault trees may be required to evaluate all the potential failures associated with a system.

To use the FTA technique, the components within the system under analysis must be independent. If the characteristics of the system are such that this assumption is not valid, then an alternative approach is required (refer to the section titled “Related Techniques”).

The fault tree has a specified treelike form, starting at the top with the system failure under analysis. The tree is built downward from this undesired event using deductive logic, a “what can cause this” approach, into its intermediate causes. The key to the visual nature of the approach is the descriptions used to document the events, as the logic is developed. The branches of the tree terminate with component failures (often referred to as basic events). Figure 1 illustrates a typical fault tree structure.

The basic elements of the fault tree are gates and events. Gates describe the fault logic between events. There are a number of different types of gates, each representing a causal relationship. The most common gate symbols are OR and AND (shown in Figure 1). The output of an OR gate, represented by the event described above the gate symbol, will occur if at least one of the input events (represented below the gate symbol) occurs, and for an AND gate then all input events must occur.

The other main element of the fault tree is the event. The most common events are intermediate and basic events (shown in Figure 1). All basic events have a distinct labeling or code on the tree

and are represented by circles. Data, in terms of failure and repair information, is required for these events. It is the probability of these basic event failures that can be used to calculate quantitative measures for the system, i.e., the probability of system failure.

Construction of the Fault Tree

To develop the inputs to each event the *immediate*, *necessary*, and *sufficient* causes need to be defined. This is often referred to as the *immediate cause effect*. Immediate refers to considering the next level of resolution or the next linked components in the system, and hence only taking small steps in the analysis. Necessary means making sure that all failures included are needed to cause the output event and that no redundant failures are included. Sufficient means that no failures are omitted from the input list. The immediate, necessary, and sufficient causes of the top event (TOP) then become subevents or intermediate events, where the same process is repeated until basic event inputs are reached on all branches.

When trying to construct a fault tree it may take a couple of attempts. After each attempt the logic of the diagram needs to be checked against your understanding of the system mechanics. The exact representation of the diagram may be different if drawn by different analysts, but will be equivalent if the logic is the same, namely, if the failure combinations are identical.

Qualitative Analysis

The qualitative phase of FTA is involved with determining the failure combinations that result in the system failure defined at the top of the tree. These failure combinations are known as *cut sets* or *minimal cut sets*. A *cut set* is a list of failure events such that if they occur, then so does the top event. A *minimal cut set* is a list of minimal, necessary, and sufficient conditions for the occurrence of the top event; basically, it is a cut set such that if any component failure event is removed from the combination it will no longer cause the system failure (see **Path Sets and Cut Sets in System Reliability Modeling**).

Establishing the minimal cut sets can then be used to form a logic expression for the top event. The

Figure 1 Example fault tree structure

minimal cut set expression for the top event (TOP) is such that $TOP = C1 + C2 + \dots + Cn$ where Ci are the minimal cut sets, with n in total, and “+” is the logical OR.

There are a number of methods that can be used to find these failure combinations, and the one most frequently used is the top-down approach (for other methods see reference [2]). For implementation, laws of Boolean algebra are required. The four laws needed are (a) the distributive law, (b) the idempotent law to remove repeated cut sets, (c) the idempotent law to remove repeated failure events, and (d) the absorption law to remove redundant combinations: Note a dot (.) refers to AND logic.

$$(A + B).(C + D) = A.C + A.D + B.C + B.D \text{ (a) (1)}$$

$$A + A = A \text{ (b) (2)}$$

$$A.A = A \text{ (c) (3)}$$

$$A + A.B = A \text{ (d) (4)}$$

The top-down approach incorporates four main steps:

- Step 1: Start at top of tree.
- Step 2: Express the top event in terms of its inputs using Boolean algebra.
- Step 3: Expand and simplify the expression using laws of Boolean algebra, if possible.
- Step 4: Substitute an expression for each gate working down through the tree and each time repeat step 3.

The fault tree in Figure 1 is used to demonstrate these steps. Step 1 involves starting at the top of the tree, i.e., at TOP. The inputs of TOP, step 2, are two intermediate events G1 and G2. The logical relationship between them is an OR gate, and therefore TOP can be expressed as $TOP = G1 + G2$. No simplification, using the laws of Boolean algebra, is necessary in this example for step 3. Step 4 in the process then considers G1 and G2 in turn, expressing these gates using Boolean algebra. G1 has inputs P1F and P2F. These are related using an AND gate, therefore the expression will involve the dot (.) symbol. Hence $G1 = P1F.P2F$. Substituting this expression to that for TOP gives $TOP = (P1F.P2F) + G2$. Next consider G2. Its inputs are P3F and LB, connected using an OR gate. Therefore, the expression for G2 is $P3F + LB$. Substituting this into the expression for TOP gives $TOP = P1F.P2F + P3F + LB$. No expansion or Boolean algebra simplification is required. Therefore the top event, pumping system failure, will occur if both Pump 1 and Pump 2 fail together, if Pump 3 fails on its own, or if the line is blocked.

Quantification

For a system to be deemed as having attained certain safety standards, a numerical analysis is required. There are a number of system performance measures that can be calculated using the fault tree analysis technique. These include calculating the system probability of failure, frequency of failure, **system**

downtime, and expected number of failures [2, 3]. The focus in this overview is on the approach for calculating the probability of system failure. As the state of components or the system cannot be predicted exactly, the use of **probability theory** is required to predict the likelihood of occurrence or nonoccurrence. In general terms, probability is a measure of the likelihood that a particular event will occur in any one experiment carried out in prescribed conditions. In terms of the reliability analysis of systems, the “particular event” refers to the component failure or system failure, with the “prescribed conditions” being the manner in which they function or are operated. When calculating the exact top event probability, the formula, referred to as the inclusion–exclusion expansion, equation (5), is used whereby successive consideration is given to the probability of failure of additional multiple minimal cut set combinations (an extension of the addition law of probability [4]). The first summation term refers to the addition of the probability of failure of each minimal cut set, the second summation to the addition of the probability of the failure of two minimal cut sets together, and so on.

$$\begin{aligned}
 &P(C_1 \text{ or } C_2 \text{ or } \dots \text{ or } C_n) \\
 &= \sum_{i=1}^n P(C_i) - \sum_{i=1}^{n-1} \sum_{j=i+1}^n P(C_i \text{ and } C_j) \\
 &\quad + \sum_{i=1}^{n-2} \sum_{j=i+1}^{n-1} \sum_{k=j+1}^n P(C_i \text{ and } C_j \text{ and } C_k) + \dots \\
 &\quad + (-1)^{n+1} P(C_1 \text{ and } C_2 \text{ and } \dots \text{ and } C_n) \quad (5)
 \end{aligned}$$

The steps to find the system failure probability can be listed as follows:

1. Find the top event logic expression.
2. Apply the inclusion–exclusion formula to obtain the probability expression.
3. Substitute in probabilities of failure for each component.

To illustrate, consider a system that has two minimal cut sets {A,B} and {B,C,E}.

1. The top event logic expression, using the minimal cut set expression is given by $TOP = A.B + B.C.E$.

2. The first term in the inclusion–exclusion formula is the summation of the probability of each single minimal cut set failure: $P(A.B) + P(B.C.E)$

The second term refers to the summation of the probability of two minimal cut set failures and is given by $P(C_1.C_2) = P(A.B.B.C.E)$, which can be simplified using the absorption law to $P(A.B.C.E)$.

Therefore the top event probability expression is given by

$$P(TOP) = P(A.B) + P(B.C.E) - P(A.B.C.E) \quad (6)$$

3. If it is assumed that the probability of failure of each component is 0.1, then the probability of the top event failure is as follows:

$$P(TOP) = 0.01 + 0.001 - 0.0001 = 0.0109 \quad (7)$$

As the number of minimal cut sets for a system failure increases, this has the effect of dramatically increasing the number of terms in the inclusion–exclusion formula. This can cause a problem even for fast modern digital computers; hence approximation methods have been derived.

The two simplest approximations are based on the principles of the inclusion–exclusion method; these are the lower and upper bounds for the top event probability. The lower bound can be calculated using the first two terms in the inclusion–exclusion principle, equation (8). The upper bound can be calculated by truncating the inclusion–exclusion formula after the first term, equation (9).

$$Q_{\text{LOWER}} = \sum_{i=1}^n P(C_i) - \sum_{i=2}^n \sum_{j=1}^{i-1} P(C_i \cap C_j) \quad (8)$$

$$Q_{\text{UPPER}} = \sum_{i=1}^n P(C_i) \quad (9)$$

For other approximations see references [2, 3].

Data

In the illustrative example, the probability of failure of each component was fixed at 0.1. The failure of a component, its unavailability or failure probability, defined as q_x , is dependent on how the component is maintained.

It is common practice to use a constant rate of failure; therefore, the exponential distribution for

times to failure is used. If the rate of failure is not constant, then the appropriate distribution is needed (see reference [2]). For a nonrepairable component the information commonly available is its rate of failure, referred to as λ . The unavailability for a nonrepairable component, x , with failure rate, λ , is given by equation (10). The “ t ” given in the exponential term of the equation refers to the length of operation. Any units of measurement can be used, i.e., hours or years, as long as all parameters use the same measurement.

For components that are repairable, then the extra piece of information known is the repair rate (ν). For these components the maintenance adopted is usually unscheduled, meaning that when the component fails it will be immediately repaired. To calculate the unavailability for this type of component equation (11) is used.

$$q_x = 1 - e^{-\lambda t} \quad (10)$$

$$q_x = \frac{\lambda}{\lambda + \nu} (1 - e^{-(\lambda + \nu)t}) \quad (11)$$

The other type of maintenance is scheduled maintenance, whereupon the component will be checked for failure at specified intervals, usually typical of standby or safety components. For this type of maintenance, an inspection interval (θ) is also available. Often an average unavailability is calculated for the component, using the simplest formula given in equation (12). If a failure occurs between two inspections, the precise time of failure is not known, hence the formula, equation (12), assumes that on average it occurs half way through the interval, hence the inclusion of $\theta/2$. More exact equations for this type of maintenance are available [2, 3].

$$q_x = \lambda \left(\frac{\theta}{2} + \tau \right) \quad (12)$$

Therefore, the probability of failure of each component in the system is evaluated using one of equations (10)–(12). This value is then used in calculating the system failure probability. Typical data available for components can be found in reference [5].

Advances in the Technique

Besides the standard qualitative and quantitative analysis that can be performed, the technique has developed to incorporate importance measures [2, 6], initiator and enabler theory [2], FTA on computers

with graphical user interfaces, automatic fault tree construction and binary decision diagrams [7]. Importance measures developed by researchers Birnbaum, Esary, Proschan, Fussel, and Vesely give a ranking for components in terms of their contribution to causing a system failure. Initiator and enabler theory (developed by Lambert and Dunglinson) gives a limited capability for the technique to deal with the order in which components fail (*see also Component Reliability Importance*). With the technique being so well developed, a number of commercial computer packages are widely available. The latest development in this area has been in terms of the analysis process and a more efficient mechanism, referred to as the binary decision diagram approach, has been developed to improve on the traditional kinetic tree theory.

Related Techniques

FTA provides one tool in an armory of tools that can be used to assess the risk and reliability of a system. Often the first step to understand the system and its components is to use the **FMEA** technique (failure mode and effects analysis, *see Failure Modes and Effects Analysis*), where critical system failure modes identified are further considered using more detailed approaches depending on the system characteristics. The fault tree approach is primarily suitable for independent systems. If the system under analysis involves a sequence of events, the technique of event tree analysis [2, 3] may be more suitable. If the system contains dependencies, the method of Markov analysis can be used to find the reliability of the system [2, 3]. For systems with even more complex characteristics, **Monte Carlo simulation** may be the way forward (*see Path Sets and Cut Sets in System Reliability Modeling*). It is key that the technique used to analyze the system is chosen depending on the characteristics of the systems.

System Reliability: Monte Carlo Estimation

Introduction

We discuss three situations where **Monte Carlo** simulation can be used to assess system reliability or availability.

First, consider an n -component coherent system (see **Coherent Systems**) having components whose reliabilities can be expressed in the vector $\mathbf{p} = (p_1, p_2, \dots, p_n)$. The system reliability is then a function of the component reliabilities, so we write

$$r(\mathbf{p}) = P(\text{system functions if components have reliabilities } \mathbf{p}) \quad (1)$$

For series, parallel, or **series-parallel systems**, it is straightforward to compute system reliability as a function of component reliabilities. (See **Parallel, Series, and Series-Parallel Systems**.) Many other system configurations, especially when the number of components is not large, lead to closed-form expressions for system reliability. However, if the number of components is large, or the system configuration is complex, closed-form expressions may be difficult to get and **Monte Carlo simulation** may be preferable.

Second, if component reliabilities are not known, but rather estimated on the basis of a number of pass/fail tests, then system reliability must be estimated from **component reliability**. Lower confidence limits for system reliability are difficult to obtain analytically. The **bootstrap** can be used to obtain lower confidence bounds [1]. Alternatively, if a Bayesian approach is taken, we can use Monte Carlo simulation to draw samples from the posterior distribution of the system reliability.

Third, there are many measures of system performance that can be estimated only through simulation. We consider, for example, the case of a one-component system with one stand-by unit and one repair server. This situation can be modeled with **queues** (see **Queues in Reliability**). The availability $A(t)$ is defined to be the probability that the system is up (operating) at time t . Availability can be evaluated analytically only in the simplest cases; otherwise, a Monte Carlo simulation is required.

Reliability for Complex System

When a system's configuration diagram is complex, it may be difficult to compute system reliability even if all component reliabilities are known. Consider, for example, the "bridge" system in Figure 1. (This system is not that complicated and, in fact, the system reliability could be computed directly, but it will due for illustration.)

For this system, the minimal cut sets, that is, minimal sets of components whose failure guarantees the failure of the system, are $\{1, 2\}$, $\{4, 5, 6, 7\}$, $\{1, 3, 6, 7\}$, and $\{2, 3, 4, 5\}$. If we let $X_i = 1$ if component i is working, and 0 otherwise, then the structure function for this system is

$$\begin{aligned} \phi(x_1, x_2, \dots, x_7) = & [1 - (1 - x_1)(1 - x_2)] \\ & \times [1 - (1 - x_4)(1 - x_5)(1 - x_6)(1 - x_7)] \\ & \times [1 - (1 - x_1)(1 - x_3)(1 - x_6)(1 - x_7)] \\ & \times [1 - (1 - x_2)(1 - x_3)(1 - x_4)(1 - x_5)] \end{aligned} \quad (2)$$

If we let $r_i = P(X_i = 1)$, $i = 1, 2, \dots, 7$ denote the component reliabilities, we can use Monte Carlo simulation to estimate the system reliability by simulating the performance of each component, obtaining simulated values for $x_1, x_2, \dots, x_7$. For illustration, suppose that the component reliabilities are

$$r_1 = r_2 = 0.9 \quad (3)$$

$$r_3 = 0.99 \quad (4)$$

$$r_4 = r_5 = r_6 = r_7 = 0.95 \quad (5)$$

We ran 100 000 simulations, and 98 986 times the system was successful. Our estimate for the system reliability is therefore

$$\hat{r} = \frac{98\,986}{100\,000} = 0.98986 \quad (6)$$

In this example, most simulations resulted in all components working, in which case the system is sure to work. If we could focus attention on a smaller set of possible values, for example those outcomes with at least one failure, then we might eliminate much of the work and therefore be able to run more simulations in the same amount of time. This is the concept of *restricted-sampling Monte Carlo*, developed by Kumamoto *et al.* [2], and described in Henley and Kumamoto [3]. If there are n components, let S

Figure 1 Structure diagram of a bridge system

Figure 2 Restricted-sampling Monte Carlo

denote the set of all 2^n possible outcomes for the system. The key idea is to find sets U and L , which are subsets of all possible outcomes, in such a way that these sets, respectively, contain and are contained in the set F . The set U consisting of all outcomes where at least one component has failed and the set L consisting of the outcome where all components fail will always work, although more efficient choices may be made in particular cases. We must be able to compute P_U and P_L , the system reliabilities for outcomes U and L . Figure 2 illustrates the idea.

If we could then restrict our simulated values to be contained in the set $U \setminus L$, we could avoid the vast number of simulations where all components worked and hence the system worked. If we found that M outcomes out of the N simulations fell in the set $F - L$, then we would have

$$\frac{M}{N} = \text{estimate of } \frac{P_F - P_L}{P_U - P_L} \quad (7)$$

Since we know P_U and P_L , we can obtain

$$\text{estimate of } P_F = P_L + \frac{M}{N} (P_U - P_L) \quad (8)$$

Other methods of reducing computation time are discussed in [2] and [3].

Estimating System Reliability from Component Data

Suppose now that the component reliabilities are not known, and are estimated from testing. We assume that a pass/fail testing is done and that for component i , the number of passing components is y_i out of n_i that were tested. Since, given the component reliability r_i for component i we know that y_i has a binomial distribution with parameters n_i and r_i . The maximum likelihood estimate (MLE) of the system reliability is thus

$$\hat{r}_i = \frac{y_i}{n_i} \quad (9)$$

We could easily obtain (assuming that the system is not too complex) a point estimate for system reliability by substituting the estimates of the component reliabilities into the system reliability function. However, it is a remarkably difficult problem to find a lower confidence bound on the system reliability, even for simple systems like a three-component series system. Martz and Duran [4] and Leemis [1] have investigated this problem. Leemis has proposed using the bootstrap to find a lower confidence bound for system reliability. The bootstrap involves repeatedly resampling (with replacement) from the sample. He suggests some modifications for the case where a component passes all tests ($y_i = n_i$).

A fully Bayesian approach is suggested in Martz and Waller [5]. The likelihood for the data from component i is

$$L(r_i | y_i) = c r_i^{y_i} (1 - r_i)^{n_i - y_i} \quad (10)$$

For the binomial distribution, the natural conjugate prior distribution is the beta (denoted $\text{BETA}(\alpha_i, \beta_i)$), which has probability density function (PDF)

$$p(r_i) = c r_i^{\alpha_i - 1} (1 - r_i)^{\beta_i - 1}, \quad 0 < r_i < 1 \quad (11)$$

The posterior is then

$$p(r_i | y_i) = c r_i^{y_i + \alpha_i - 1} (1 - r_i)^{n_i - y_i + \beta_i - 1}, \quad 0 < r_i < 1 \quad (12)$$

which is the BETA ($y_i + \alpha_i, n_i - y_i + \beta_i$) distribution. If for example, we had a three-component series system, the system reliability would be

$$\text{System reliability} = r_1 r_2 r_3 \quad (13)$$

The posterior distribution of the quantity $r = r_1 r_2 r_3$ is rather messy, and it may be preferable to take Monte Carlo samples from it.

Suppose, for the sake of illustration, that the components for the three-component series system are believed, *a priori*, to be rather reliable with, say, a reliability of around 0.9. Thus we choose for a prior a distribution that has mean 0.9, but still has reasonable spread. The mean of the BETA(α, β) is $\alpha / (\alpha + \beta)$. Thus any combination of α and β satisfying $\alpha / (\alpha + \beta) = 0.9$ would work, but the larger α and β are, the smaller the variance. The choice of $\alpha = 18$, $\beta = 2$ gives the prior shown in Figure 3.

Suppose also that the components have undergone testing, with the results as shown in Table 1.

We ran 100 000 simulations from the posterior distribution of the system reliability, which for the series system is $r = r_1 r_2 r_3$. A histogram, which should approximate the posterior distribution, is shown in Figure 4. The lower **percentiles** for the posterior distribution are $p_{0.01} = 0.6836$, $p_{0.05} = 0.7362$, and

$p_{0.10} = 0.7620$. These numbers would serve as lower Bayesian confidence limits for the system reliability.

For more complicated systems, the method described here would be similar, except the system reliability function would be more complicated. For example, if the system were a 3-out-of-4 system, then the system reliability would be

$$r = 1 - \left[\prod_{i=1}^4 (1 - r_i) + \sum_{i=1}^4 r_i \prod_{\substack{j=1 \\ j \neq i}}^4 (1 - r_j) \right] \quad (14)$$

The procedure for estimating system reliability would be similar: collect data on each component, compute the posterior distribution for each component, simulate from each posterior, and compute the expression in equation (14).

For complicated models, especially hierarchical models (i.e., models where there are **prior distributions** on the parameters of the prior distribution), the posterior distribution cannot be found directly. In such cases, Markov Chain Monte Carlo (MCMC) methods can be used to draw samples from the posterior distribution. See Gilks *et al.* [6].

Figure 3 Prior distribution for component reliability

Figure 4 Monte Carlo estimate of posterior distribution

Table 1 Prior distributions, test data, and posterior distribution for example

i	Prior parameters		Test data		Posterior distribution	Posterior mean
	α_i	β_i	n_i	y_i		
1	18	2	100	97	BETA(115, 5)	0.95833
2	18	2	25	24	BETA(43, 3)	0.93478
3	18	2	10	10	BETA(28, 2)	0.93333

System Availability

Measures of system effectiveness, such as availability, are often complicated to evaluate unless the simplest assumptions are made. Even though many measures of system effectiveness, such as availability, can be evaluated in the context of queuing models (*see Queues in Reliability*), even these queuing models become too complicated to be evaluated analytically.

Consider for instance a one-component system with one component available as a standby. Switching over is instantaneous, but there is only one repair person, so if both the components are in a failed state, then the system is down. We make the following assumptions about the failure and repair times.

1. Times to failure for system 1 are independent and identically distributed (i.i.d.) and have cumulative distribution function (cdf) $F_1(x)$.
2. Times to failure for system 2 are i.i.d. and have cdf $F_2(x)$.
3. Repair times for system 1 are i.i.d. and have cdf $G_1(x)$.
4. Repair times for system 2 are i.i.d. and have cdf $G_2(x)$.
5. All failure times and repair times are independent.

The assumption 5 about the independence of failure and repair times can be weakened, but for now we will consider this case. Under these assumptions, each system can be in one of the four states:

W – working
 S – operable, but in standby mode
 R – failed and being repaired
 Q – failed and queued for repair.

Although it might seem like there would be $4 \times 4 = 16$ possible states for the system (since the overall system is comprised of two systems), there are actually only six possible states. They are

State 1: WS
 State 2: RW
 State 3: SW
 State 4: RQ
 State 5: WR
 State 6: QR

The possible state transitions are shown in Figure 5.

Figure 5 State diagram for one component plus standby system

We will let $X_1, X_2, \dots$ and $Y_1, Y_2, \dots$ denote the sequences of failure times for systems 1 and 2, respectively, and we will let $R_1, R_2, \dots$ and $S_1, S_2, \dots$ denote the corresponding repair times for systems 1 and 2, respectively. If the system begins in state 1 (WS), the failure of system 1 causes an immediate switch to system 2 and the commencement of repair for system 1. This is a transition to state 2. The next state depends on which happens first: the repair of system 1 or the failure of system 2. In the former case, the overall system moves to state 3 (SW), and in the latter case, the overall system moves to state 4 (RQ). In terms of the random variables defined above, the overall system transitions from state 2 to 3 if $R_1 < Y_1$ and from state 2 to 4 if $Y_1 > R_1$. Either way, the next state must be state 5 (WR). The rest of the transitions are similar.

Monte Carlo simulation can then be done by randomly generating the random variables: $X_1, X_2, \dots, Y_1, Y_2, \dots, R_1, R_2, \dots$ and $S_1, S_2, \dots$. We must then keep track of the sequence of states and the actual event times (where an event occurs whenever there is a transition from one state to another). Note that the overall system is down in states 4 and 6, and the system is up otherwise. We could estimate the long run unavailability by counting the “down” time and dividing it by the total time. For illustration, we did this under several different scenarios, as described in Table 2.

The simulations shown in Table 2 were done in Matlab. There are several packages that specialize in simulation which can be used to create similar models. For example, in Arena, the “Preempt” module can be used to switch machines after a failure, while the “Tally” can report the total downtime. Other

Table 2 Estimation of average downtime or unavailability for various failure repair distributions

Distribution of X_i	Distribution of Y_i	Distribution of R_i	Distribution of S_i	Average downtime
Exponential(1)	Exponential(1)	Exponential(0.5)	Exponential(0.5)	14.18%
Exponential(1)	Exponential(1)	Exponential(0.4)	Exponential(0.4)	10.13%
Exponential(1)	Exponential(1)	Exponential(0.3)	Exponential(0.3)	6.39%
Exponential(1)	Exponential(1)	Exponential(0.1)	Exponential(0.5)	8.01%
Gamma(1,4)	Gamma(1,4)	Gamma(0.5,3)	Gamma(0.5,3)	1.86%
Gamma(1,4)	Gamma(1,4)	Gamma(0.3,3)	Gamma(0.3,3)	0.31%
Gamma(3,4)	Gamma(3,4)	Gamma(1,3)	Gamma(1,3)	0.43%
Gamma(6,4)	Gamma(3,4)	Gamma(1,3)	Gamma(1,3)	0.15%
Weibull(6,2)	Weibull(6,2)	Gamma(1,3)	Gamma(1,3)	7.00%
Weibull(6,2)	Weibull(7,2)	Gamma(0.5,3)	Gamma(0.5,3)	1.13%

packages, such as ProModel and Flexsim, need similar modifications to create the model.

Convergence of Monte Carlo Methods

Typically a large number, say N , simulations are run and the quantity of interest is estimated from the result of these N simulations. In most cases, including all of those discussed here, the estimated value converges to the true value as $N \rightarrow \infty$. Convergence is often slow, however, with the **standard error** being proportional to $1/\sqrt{N}$.

Repairable Systems: Statistical Inference

Introduction

A repairable system is a system which, upon experiencing failure, is brought back to working condition by any corrective measure other than replacement of the whole system. Examples of **repairable systems** abound in the literature. Some of the commonly cited datasets include the aircraft air conditioning data first presented in Proschan [1], the bus motor failure data analyzed by Davis [2], the **software system failures** examined in Musa [3], and the failures of load-haul-dump (LHD) machines used in underground mines in Sweden and presented in Blischke and Murthy [4, Table 2.7].

In modeling repairable systems, the common assumption of independent and identically distributed (i.i.d.) observations will typically not hold. The failure distribution of a repaired system is, in general, different from that of a new system since the failure distribution of a repaired system depends on the age at failure as well as the type of repair performed. The two types of repair most commonly found in the literature are perfect repair and minimal repair. A perfect repair restores a system to the good-as-new state. Assuming that a perfect repair is performed at each failure results in times between failures being i.i.d. Hence the renewal process is an appropriate model to employ. In particular, if the common distribution of the times between failures is taken to be the exponential distribution, then one gets the homogeneous **Poisson process** (HPP). On the other hand, a minimal repair brings a system back to its working state just prior to failure. If it is assumed that a minimal repair is undertaken at each failure, then the nonhomogeneous Poisson process (NHPP) is the model of choice.

In addition to the renewal process and the NHPP, various models for repairable systems have been proposed and continue to be proposed in the literature. Dorado *et al.* [5] proposed a general class of **imperfect repair** models that includes the ones introduced by Brown and Proschan [6], Block *et al.* [7], and Kijima [8]. A class of models using the concept of virtual ages was proposed by Last and Szekli [9]. More recently, Lindqvist *et al.* [10] examined

heterogeneous trend renewal processes, while Peña and Hollander [11] discussed dynamic models for recurrent events that are applicable in both the repairable systems scenario as well as in medical settings. Both papers presented very general models that include most of the existing models as special cases.

In this article, the main interest is in statistical inference procedures for repairable systems. In particular, the issues of estimation and goodness-of-fit testing will be addressed. Since it is virtually impossible to present inference procedures for all models, we will focus on the HPP, NHPP, and a generalized age-dependent minimal repair model. The age-dependent minimal repair model, a model that subsumes both the HPP and NHPP, was originally proposed by Block *et al.* [7].

This paper is organized as follows. In the section titled “Inference Procedures for Homogeneous and Nonhomogeneous Poisson Processes”, we present estimation procedures for the HPP and the NHPP. In the section titled “**Age-Dependent Minimal Repair Models**”, we describe the model of interest and formulate it in terms of the counting process framework. We discuss the estimation of unknown parameters in the section titled “Point Estimation” and address goodness-of-fit testing in the section titled “Goodness-of-Fit Testing”. Finally, we present some possible extensions as well as ongoing research in the section titled “Concluding Remarks”.

Inference Procedures for Homogeneous and Nonhomogeneous Poisson Processes

In this section, we tackle the estimation problem for the two basic models for repairable systems. The method of maximum likelihood will be used to find estimators. We will consider both the failure-truncated and the time-truncated scenarios. The observed data are said to be failure-truncated if the testing of the repairable system ceases after a prespecified number of failures. On the other hand, the data are said to be time-truncated if the testing stops at a prespecified time. We will focus on the case where we observe several failures in a single repairable system.

Homogeneous Poisson Process

Let $T_1, T_2, \dots$ denote the time of the i th failure

2 Repairable Systems: Statistical Inference

and let $X_1, X_2, \dots$ denote the times between failures. The failure times can then be represented as $T_1 = X_1, T_2 = X_1 + X_2, \dots, T_k = X_1 + X_2 + \dots, X_k, \dots$. A perfect repair being undertaken at each failure results in i.i.d. interfailure times. Suppose we assume that the times between failures follow an $EXP(\theta)$ distribution, that is, the probability density function of X_i is given by $f(x) = (1/\theta) \exp(-x/\theta), x > 0, \theta > 0$. We then have an HPP with **intensity function** $\lambda(t) = 1/\theta, t > 0$. Note that the HPP models the situation where the system neither deteriorates nor improves over time.

Let us now derive the maximum-likelihood estimate for θ . If the system is tested until n failures are obtained, then the observed failure times are $0 < t_1 < t_2 < \dots < t_n$. The likelihood and log-likelihood functions are given by

$$L(\theta|t) = \left(\frac{1}{\theta}\right)^n e^{-t_n/\theta} \quad \text{and} \\ \ell(\theta|t) = -n \ln \theta - \frac{t_n}{\theta} \quad (1)$$

respectively. Taking the derivative of the log-likelihood function with respect to θ and setting the derivative equal to zero results in $\hat{\theta} = t_n/n$. Consequently, by the invariance property of maximum-likelihood estimators, the maximum-likelihood estimate of $\lambda(t_n)$ is $\hat{\lambda}(t_n) = 1/\hat{\theta} = n/t_n$.

If we want to come up with a $(1 - \alpha)100\%$ **confidence interval** (CI) for θ , then we need to examine the distribution of T_n . Since $T_n = X_1 + X_2 + \dots + X_n$, where X_i 's are i.i.d. $EXP(\theta)$, then it follows that T_n has a gamma distribution with scale parameter θ and shape parameter n . Thus, the random variable $2T_n/\theta$ has a χ^2 distribution with $2n$ **degrees of freedom**. If we let $\chi_p^2(u)$ denote the 100 p th percentile of a χ^2 distribution with u degrees of freedom, we obtain

$$\mathbf{P} \left[\chi_{\alpha/2}^2(2n) < \frac{2T_n}{\theta} < \chi_{1-\alpha/2}^2(2n) \right] = 1 - \alpha \quad (2)$$

Hence, a $(1 - \alpha)100\%$ CI for θ is $(2t_n/\chi_{1-\alpha/2}^2(2n), 2t_n/\chi_{\alpha/2}^2(2n))$.

Example 1 For the purpose of illustration, let us take the failure times for Aircraft 3 in the aircraft air conditioning data set first examined in [1]. The

original data were given in terms of the times between failures. Suppose we observe the aircraft until $n = 20$ failures have occurred. The observed failure times are

90 100 160 346 407 456 470 494 550 570
649 733 777 836 865 983 1008 1164 1474 1550

The estimated mean time between failures is then $\hat{\theta} = 1550/20 = 77.5$. In addition, a 90% CI for θ is given by

$$\left(\frac{2t_n}{\chi_{0.95}^2(40)}, \frac{2t_n}{\chi_{0.05}^2(40)} \right) = \left(\frac{2(1550)}{55.7585}, \frac{2(1550)}{26.5093} \right) \\ = (55.5969, 116.9401) \quad (3)$$

We can therefore conclude, with 90% confidence, that the mean time between failures is somewhere between 55.5969 and 116.9401.

Let us now consider the situation where the system is tested until a prespecified time t resulting in observed data $t_1 < t_2 < \dots < t_N < t$. Note that the number of observed failures, denoted by N , is a random variable which follows a Poisson distribution with mean t/θ . Given that $N = n$, the likelihood and log-likelihood functions are given by

$$L(\theta|n, t) = \frac{(t/\theta)^n \exp^{-t/\theta}}{n!} \quad \text{and} \\ \ell(\theta|n, t) = n \ln t - n \ln \theta - t/\theta - \ln n! \quad (4)$$

respectively. Taking the derivative of the log-likelihood function with respect to θ and equating it to zero yields the maximum-likelihood estimator $\hat{\theta} = t/N$. To come up with a $(1 - \alpha)100\%$ CI for θ , we use the result of Pearson and Hartley [12] involving a $(1 - \alpha)100\%$ CI for t/θ . They proved that if $N = n$ failures are observed, then a $(1 - \alpha)100\%$ CI for t/θ is $(1/2\chi_{\alpha/2}^2(2n), 1/2\chi_{1-\alpha/2}^2(2n + 2))$. Consequently, a $(1 - \alpha)100\%$ CI for θ is given by

$$\left(\frac{2t}{\chi_{1-\alpha/2}^2(2c + 2)}, \frac{2t}{\chi_{\alpha/2}^2(2c)} \right)$$

Example 2 Consider the same data set examined in Example 1 but assume that we observed the aircraft until $t = 1575$. Note that with this particular choice

of t , we end up with exactly the same set of failure times as in Example 1. Our point estimate of θ , however, changes to $\hat{\theta} = 1575/20 = 78.75$. It then follows that a 90% CI for θ is

$$\left(\frac{2t}{\chi_{0.95}^2(42)}, \frac{2t}{\chi_{0.05}^2(40)} \right) = \left(\frac{2(1575)}{58.1240}, \frac{2(1575)}{26.5093} \right) \\ = (54.1945, 118.8262) \quad (5)$$

Thus we conclude, with 90% confidence, that the mean time between failures lie between 54.1945 and 118.8262. It is worthwhile to note that the estimates change depending on how the observed data were generated.

Nonhomogeneous Poisson Process

Let us now examine the scenario where a minimal repair is performed at each failure thereby resulting in the nonhomogeneous Poisson process as the appropriate model. In contrast to the HPP, the NHPP is capable of modeling systems which wear out or improve over time. In particular, if we let the intensity function of the NHPP be of the form

$$\lambda(t; \gamma, \theta) = \frac{\gamma}{\theta} \left(\frac{t}{\theta} \right)^{\gamma-1}, \quad \theta > 0 \quad (6)$$

then we obtain the power law process, a widely used model in the repairable systems setting owing to its flexibility. For instance, a deteriorating system can be modeled by taking $\gamma > 1$, while an improving system can be modeled by assuming a value of $\gamma < 1$. Note that taking $\gamma = 1$ allows us to recover an HPP with intensity $1/\theta$.

Suppose the repairable system is observed until n failures occur. Then the observed failure times are $t_1, t_2, \dots, t_n$, where n is fixed. The joint **probability density function** of the failures times $T_1, T_2, \dots, T_n$ for a failure-truncated NHPP with intensity function $\lambda(t)$ is

$$f(t_1, t_2, \dots, t_n) = \left[\prod_{i=1}^n \lambda(t_i) \right] \exp \left[- \int_0^{t_n} \lambda(s) ds \right], \\ 0 < t_1 < t_2 < \dots < t_n \quad (7)$$

Consequently, the likelihood function for the power law process can be expressed as

$$L(\gamma, \theta | \mathbf{t}) = \frac{\gamma^n}{\theta^{n\gamma}} \left[\prod_{i=1}^n t_i \right]^{\gamma-1} \exp \left[- \left(\frac{t_n}{\theta} \right)^\gamma \right], \\ 0 < t_1 < t_2 < \dots < t_n \quad (8)$$

with corresponding log-likelihood function given by

$$\ell(\gamma, \theta | \mathbf{t}) = n \ln \gamma - n\gamma \ln \theta \\ + (\gamma - 1) \sum_{i=1}^n \ln t_i - \left(\frac{t_n}{\theta} \right)^\gamma \quad (9)$$

Taking the partial derivatives of the log-likelihood function with respect to γ and θ and equating them to zero results in

$$\frac{n}{\hat{\gamma}} - n \ln \hat{\theta} + \sum_{i=1}^n \ln t_i - \left(\frac{t_n}{\hat{\theta}} \right)^{\hat{\gamma}} \ln \left(\frac{t_n}{\hat{\theta}} \right) = 0 \quad \text{and} \\ \frac{\hat{\gamma} t_n^{\hat{\gamma}}}{\hat{\theta}^{\hat{\gamma}+1}} - \frac{n \hat{\alpha}}{\hat{\theta}} = 0 \quad (10)$$

respectively. Solving the system of equations simultaneously yields the maximum-likelihood estimates

$$\hat{\gamma} = \frac{n}{\sum_{i=1}^n \ln \left(\frac{t_n}{t_i} \right)} \quad \text{and} \quad \hat{\theta} = \frac{t_n}{n^{1/\hat{\gamma}}} \quad (11)$$

To develop an interval estimate for γ , we use the fact that $2n\gamma/\hat{\gamma}$ follows a χ^2 distribution with $2(n-1)$ degrees of freedom (see [13, Theorem 31]). Consequently, we can write the probability statement

$$\mathbf{P} \left[\chi_{\alpha/2}^2(2(n-1)) \leq \frac{2n\gamma}{\hat{\gamma}} \leq \chi_{1-\alpha/2}^2(2(n-1)) \right] \\ = 1 - \alpha \quad (12)$$

A few algebraic manipulations yield a $(1-\alpha)100\%$ CI for γ given by

$$\left(\frac{\hat{\gamma}}{2n} \chi_{\alpha/2}^2(2(n-1)), \frac{\hat{\gamma}}{2n} \chi_{1-\alpha/2}^2(2(n-1)) \right) \quad (13)$$

4 Repairable Systems: Statistical Inference

The parameter θ has no simple interpretation and hence, CIs for θ are usually not of interest.

Example 3 Let us consider an excerpt from the software system failures dataset originally presented in [3]. The data consist of failure times, measured in execution time in CPU seconds, of a real-time command and control software system. Suppose we observed the system until $n = 20$ failures were realized resulting in the following failure times

3 33 146 227 342 351 353 444 556 571
709 759 836 860 968 1056 1726 1846 1872 1986

The point estimates of γ and θ are therefore

$$\begin{aligned}\hat{\gamma} &= \frac{20}{29.9260} = 0.668315 \quad \text{and} \\ \hat{\theta} &= \frac{1986}{20^{1/0.668315}} = 22.451613\end{aligned}\quad (14)$$

It should not be surprising that the estimated value of γ is less than one. An examination of the data reveals that the times between failures seem to be increasing which is an indication of a system that is improving over time. A 95% CI for γ is then given by

$$\begin{aligned}&\left(\frac{\hat{\gamma}}{2n}\chi_{0.025}^2(38), \frac{\hat{\gamma}}{2n}\chi_{0.975}^2(38)\right) \\ &= \left(\frac{0.668315(22.8785)}{40}, \frac{0.668315(56.8955)}{40}\right) \\ &= (0.382251, 0.950603)\end{aligned}\quad (15)$$

Hence, using a method that captures the true value of γ 95% of the time, we estimate that γ lies between 0.382251 and 0.950603.

Let us now examine the time-truncated case so that our observed values are $0 < t_1 < t_2 < \dots < t_N < t$. Keeping in mind that the number of observed failures N is a random variable, the likelihood and log-likelihood functions, given $N = n$ and $\mathbf{t}$, are

$$\begin{aligned}L(\gamma, \theta | n, \mathbf{t}) &= \frac{\gamma^n}{\theta^{n\gamma}} \left(\prod_{i=1}^n t_i\right)^{\gamma-1} \exp\left[-\left(\frac{t}{\theta}\right)^\gamma\right], \\ n &\geq 1, 0 < t_1 < \dots < t_n < t\end{aligned}\quad (16)$$

and

$$\begin{aligned}\ell(\gamma, \theta | n, \mathbf{t}) &= n \ln \gamma - n\gamma \ln \theta \\ &+ (\gamma - 1) \sum_{i=1}^n \ln t_i - \left(\frac{t}{\theta}\right)^\gamma\end{aligned}\quad (17)$$

respectively. Taking the partial derivatives of the log-likelihood function with respect to γ and θ , equating them to zero, and solving the resulting system of equations yields the maximum-likelihood estimators

$$\hat{\gamma} = \frac{N}{\sum_{i=1}^N \ln\left(\frac{t}{T_i}\right)} \quad \text{and} \quad \hat{\theta} = \frac{t}{N^{1/\hat{\gamma}}}\quad (18)$$

An interval estimate for γ can be obtained by using the result that, conditioned on $N = n$, the quantity $2n\gamma/\hat{\gamma}$ follows a χ^2 distribution with $2n$ degrees of freedom (see [13, Theorem 32]). Thus, given $N = n$, a $(1 - \alpha)100\%$ CI for γ is

$$\left(\frac{\hat{\gamma}}{2n}\chi_{\alpha/2}^2(2n), \frac{\hat{\gamma}}{2n}\chi_{1-\alpha/2}^2(2n)\right)\quad (19)$$

Note the difference in degrees of freedom between the failure-truncated and time-truncated cases. Just as in the failure-truncated situation, there is not much interest in interval estimation for the parameter θ .

Example 4 Let us revisit the data set used in Example 3. However, we now assume that we observed the system until $t = 2000$ CPU seconds. This particular value of t was chosen to illustrate the difference in estimates between the failure-truncated and time-truncated cases. The observed failure times are exactly the same as those presented in Example 3. The resulting point estimates of γ and θ turn out to be

$$\begin{aligned}\hat{\gamma} &= \frac{20}{30.0655} = 0.665192 \quad \text{and} \\ \hat{\theta} &= \frac{2000}{20^{1/0.665192}} = 22.139031\end{aligned}\quad (20)$$

Consequently, a 95% CI for γ is

$$\left(\frac{\hat{\gamma}}{2n}\chi_{0.025}^2(40), \frac{\hat{\gamma}}{2n}\chi_{0.975}^2(40)\right)$$

$$\begin{aligned}
 &= \left(\frac{0.665192(24.4330)}{40}, \frac{0.665192(59.3417)}{40} \right) \\
 &= (0.406316, 0.986841) \quad (21)
 \end{aligned}$$

Hence, using a method that captures the true value of γ 95% of the time, we estimate that γ lies between 0.406316 and 0.986841. Note that even though we used the same set of failure times for Examples 3 and 4, we obtained different estimates depending on the type of truncation that was used.

Age-Dependent Minimal Repair Models

In practice, the type of repair that is undertaken at each failure need not be always perfect or always minimal. In this section, we formalize the age-dependent minimal repair model, hereon referred to as the *BBS model*. Suppose that at time $t = 0$, a component or system with time-to-first-failure density function f is put on test. Upon failure at time t , one of two types of repair will be undertaken: a perfect repair with probability $p(t)$ or a minimal repair with probability $1 - p(t)$. Recall that a perfect repair restores the effective age of a system to 0, while a minimal repair returns the system's effective age to what it was just before failure. The BBS model admits as special cases some of the more common models in repairable system literature. For instance, if the probability of perfect repair does not depend on time, then the imperfect repair model proposed by Brown and Proschan [6] is obtained. On the other hand, taking $p(t) = 0$ recovers the NHPP model, while assuming $p(t) = 1$ results in the i.i.d. model or the renewal model.

In most instances, the conditions under which the systems operate affect the distribution of future lifetimes. The effects of operating or environmental conditions are typically taken into account through the use of covariates. To allow for even more generality in the BBS model, we incorporate covariates via a proportional hazards model. Hence, we model the system's hazard rate function as

$$\lambda(t; \mathbf{X}) = \lambda_0(t) \psi(\mathbf{X}(t), \boldsymbol{\beta}) \quad (22)$$

where $\lambda_0(t)$ is called the *baseline hazard rate function* and $\psi(\mathbf{X}(t), \boldsymbol{\beta})$ is a function that takes into

account the effects of various factors that impact system failure through the covariates $\mathbf{X}(t)$ and regression parameters $\boldsymbol{\beta}$, which characterize the effect of the covariates. Note that we are allowing the possibility that the covariates may be time dependent. Some of the proposed forms for $\psi(\mathbf{X}(t), \boldsymbol{\beta})$ include exponential, logistic, linear, and inverse linear. In this article, we will use the **Cox proportional hazards** model [14], which postulates that the system's hazard rate function is of the form

$$\lambda(t; \mathbf{X}) = \lambda_0(t) \exp[\boldsymbol{\beta}' \mathbf{X}(t)] \quad (23)$$

We will use counting processes as the main tool in formalizing the model and developing the statistical inference procedures. The formulation of the BBS model in terms of the counting process framework is attributed to Hollander *et al.* [15].

All random entities are defined on the filtered probability space $(\Omega, \mathbf{F} = (\mathcal{F}_t : t \geq 0), \mathcal{P})$, where the filtration is typically the natural filtration. In addition, the upper endpoint of the observation period is denoted by $\tau > 0$, which may be fixed or random. Denote by $W_0 \equiv 0 < W_1 < W_2 < \dots$ the successive failure times of a system, and let $U_1, U_2, \dots$ be a sequence of i.i.d. Uniform[0,1] random variables that are independent of the failure times. Since a perfect repair returns the system to the good-as-new state, it suffices to observe a system only until the time of its first perfect repair. Hence, the sequence $(W_1, W_2, \dots, W_\nu)$, where $\nu = \inf\{k \in \{1, 2, \dots\} : U_k < p(W_k)\}$, is an epoch of the BBS model. Consider observing n independent BBS epochs which may be generated by observing n independent systems, each until the time of its first perfect repair, or observing a single system up to the time of the n th perfect repair. In the latter case, the operating time reverts to zero after each perfect repair. The sample data can then be represented by $\{W_{jk} : 1 \leq j \leq n, 1 \leq k \leq \nu_j\}$. Define the stochastic processes $N = \{N_1(t), N_2(t), \dots, N_n(t)\}$ and $Y = \{Y_1(t), Y_2(t), \dots, Y_n(t)\}$, where

$$\begin{aligned}
 N_j(t) &= \sum_{k=1}^{\infty} I\{W_{jk} \leq t \wedge W_{j\nu_j}\} \quad \text{and} \\
 Y_j(t) &= I\{W_{j\nu_j} \geq t\} \quad (24)
 \end{aligned}$$

The process $N_j(t)$ basically counts the number of minimal repairs observed until time t for the j th

system, while $Y_j(t)$ is an indicator of whether the j th system is still “at risk” at time t .

With respect to the filtration $\mathbf{F}$, the cumulative intensity function is the compensator function associated with the counting process N . Hence, if the j th system has a possibly time-dependent covariate process $X_j(\cdot)$, then the compensator of N is $A = \{(A_1(t; \xi, \beta), \dots, A_n(t; \xi, \beta))\}$ with

$$A_j(t; \xi, \beta) = \int_0^t Y_j(s) \lambda(s; \xi) \exp\{\beta' X_j(s)\} ds \quad (25)$$

where $\lambda(s; \xi)$ is some baseline hazard function, β is a $q \times 1$ vector of regression coefficients, and $X_1(s), \dots, X_n(s)$ are $q \times 1$ vectors of locally bounded predictable covariate processes. In this article, we will assume a parametric specification for the baseline hazard rate function. In order to guarantee that the waiting time to the first perfect repair is almost surely finite, we assume that

$$\int_0^\infty p(t) \lambda(t; \xi) \exp\{\beta' X_j(t)\} dt = \infty \quad (26)$$

Block *et al.* [7] showed that if condition (26) holds, then the waiting time to the first perfect repair has hazard rate function $\lambda^*(t; \xi) = p(t) \lambda(t; \xi) \exp\{\beta' X_j(t)\}$.

Point Estimation

Let us first address the issue of estimating the unknown parameters. For the estimation problem, we will use the method of maximum likelihood. Under the generalized BBS setup, the likelihood process is given by

$$L(t; \xi, \beta) = \left[\prod_{s \leq t} \prod_{j=1}^n \left[Y_j(s) \lambda(s; \xi) \times \exp\{\beta' X_j(s)\} \right]^{dN_j(s)} \right] \times \exp \left[- \sum_{j=1}^n A_j(t) \right] \quad (27)$$

where Π denotes the product integral. The product integral Π can be viewed as a continuous version of the ordinary product $\prod$, in much the same way that the integral $\int$ is a continuous version of the sum $\sum$. We refer the reader to Gill and Johansen [16] or Andersen *et al.* [17] for further details about the product integral. Consequently, the log-likelihood process is

$$\begin{aligned} \ell(t; \xi, \beta) &= \int_0^t \sum_{j=1}^n \log [Y_j(s) \lambda(s; \xi) \exp\{\beta' X_j(s)\}] \\ &\quad \times dN_j(s) - \sum_{j=1}^n A_j(t) \\ &= \sum_{j=1}^n \left[\int_0^t \log [Y_j(s) \lambda(s; \xi) \exp\{\beta' X_j(s)\}] \right. \\ &\quad \times dN_j(s) - \int_0^t Y_j(s) \lambda(s; \xi) \\ &\quad \times \exp\{\beta' X_j(s)\} ds \left. \right] \end{aligned} \quad (28)$$

The maximum-likelihood estimators of the parameters ξ and β can be obtained by direct maximization of equations (27) or (28). Depending on the form of the integrand in the likelihood or log-likelihood equations, it may be possible to get a closed-form expression for the estimators by applying the principles of calculus which involves taking the partial derivatives with respect to each parameter and then setting them to zero. However, in the event that the integrand is fairly involved, then iterative methods such as the Newton–Raphson method, or an **expectation-maximization (EM) algorithm** (*cf.*, Dempster *et al.* [18]) are some of the more common approaches. An example of an EM approach can be found in Stocker and Peña [19].

Example 5 Let us revisit the power law process that was discussed in the section titled “Nonhomogeneous Poisson Process”. Note that this model can be recovered from the BBS model by taking the no-covariate case with probability of perfect repair $p(t) = 0$ and assuming that the intensity function is of the form $\lambda(t; \gamma, \theta) = (\gamma/\theta) (t/\theta)^{\gamma-1}$. In contrast to Example 3 where we observed a single repairable system, suppose we observe n such independent

repairable systems. Let t_{ji} denote the i th failure on the j th system. Take the failure-truncated case where the j th system is observed until the k_j th failure so that the observed failure times for the j th system are $0 < t_{j1} < t_{j2} < \dots < t_{jk_j}$.

Noting that the process N_j jumps only at the failure times and the size of each jump is one, then evaluating the log-likelihood function given in equation (28) at the end of the observation period yields

$$\begin{aligned} \ell(\gamma, \alpha) &= \sum_{j=1}^n \left[\sum_{i=1}^{k_j} \log \left[\frac{\alpha}{\gamma^\alpha} t_{ji}^{\alpha-1} \right] \right. \\ &\quad \left. - \int_0^{t_{jk_j}} \frac{\alpha}{\gamma^\alpha} s^{\alpha-1} ds \right] \\ &= \log \alpha \sum_{j=1}^n k_j - \alpha \log \gamma \sum_{j=1}^n k_j + (\alpha - 1) \\ &\quad \times \sum_{j=1}^n \sum_{i=1}^{k_j} \log t_{ji} - \sum_{j=1}^n \left(\frac{t_{jk_j}}{\alpha} \right)^\beta \end{aligned} \quad (29)$$

Taking the partial derivatives with respect to α and γ and equating them to zero results in the well-known estimators

$$\begin{aligned} \hat{\gamma} &= \left(\frac{\sum_{j=1}^n t_{jk_j}}{\sum_{j=1}^n k_j} \right)^{1/\hat{\alpha}} \quad \text{and} \\ \hat{\alpha} &= \frac{\sum_{j=1}^n k_j}{\sum_{j=1}^n \left(\frac{t_{jk_j}}{\hat{\gamma}} \right)^{\hat{\alpha}} \log t_{jk_j} - \sum_{j=1}^n \sum_{i=1}^{k_j} \log t_{ji}} \end{aligned} \quad (30)$$

An examination of the above expressions reveals that an iterative algorithm needs to be employed in order to obtain the estimates. More detailed discussion concerning estimation issues, including Bayesian estimation, for the power law process is given in Rigdon and Basu [13].

Goodness-of-Fit Testing

In some instances, the problem on hand is not concerned with estimating unknown parameters, but rather with determining whether a claim about a parameter and/or distribution is valid in light of the observed data. The interest therefore shifts to **hypothesis testing**. In this section, we will discuss a particular form of hypothesis testing known as *goodness-of-fit testing*. In particular, we will focus on validating the assumption concerning the baseline hazard function in the generalized BBS model. This problem is often encountered in the engineering and operations research settings, where one is typically interested in predicting the reliability of systems, developing **maintenance policies**, and providing spare parts.

There is an abundance of goodness-of-fit procedures that can be utilized. In this article, however, we will explore the family of hazard-based smooth goodness-of-fit tests introduced by Peña [20, 21] in the i.i.d setting and extended by Agustin and Peña [22, 23] and Agustin [24] to the repairable systems scenario. The main idea in developing smooth goodness-of-fit tests is the embedding of the hypothesized hazard rate function in a larger parametric family, and subsequently forming score tests. Members of the larger parametric family are generated from smooth transformations of the members of the hypothesized class. The idea of embedding was first proposed by Neyman [25], who used density functions instead of hazard rate functions. An excellent reference for the density-based smooth goodness-of-fit tests is the book by Rayner and Best [26].

Let us first consider the simple hypothesis setting that involves testing $H_0 : \lambda(\cdot) = \lambda_0(\cdot)$ versus $H_1 : \lambda(\cdot) \neq \lambda_0(\cdot)$, where $\lambda_0(\cdot)$ is a fully specified function. Consider the embedding class for the hazard rate functions given by

$$\mathcal{A}_k = \{\lambda_k(\cdot; \theta) = \lambda_0(\cdot) \exp[\theta' \Psi(\cdot)] : \theta \in \mathbb{R}^k\} \quad (31)$$

where k is some prespecified positive integer called the *smoothing order* and $\Psi(\cdot) = (\Psi_1(\cdot), \dots, \Psi_k(\cdot))'$ is some function or process. By choosing appropriate forms for $\Psi(\cdot)$, a wide range of test statistics can be obtained. Some possibilities for $\Psi(\cdot)$ are polynomial, trigonometric, or wavelet functions. By setting $\theta = (\theta_1, \dots, \theta_k)' = \mathbf{0}$ in equation (31), the hypothesized class $\mathcal{C}$ is recovered. Thus, the hypotheses of interest

8 Repairable Systems: Statistical Inference

can be restated as

$$H_0^* : \theta = \mathbf{0}, \beta \in \mathfrak{N}^m \text{ versus } H_1^* : \theta \neq \mathbf{0}, \beta \in \mathfrak{N}^m \quad (32)$$

The family of tests is then derived by forming the score test for $H_0^* : \theta = \mathbf{0}$ and determining its distributional properties. Agustin and Peña [22] established that under H_0^* and assuming certain regularity conditions hold, the estimated score process

$$\frac{1}{\sqrt{n}} \hat{U}(\tau; \mathbf{0}, \hat{\beta}) = \frac{1}{\sqrt{n}} \sum_{j=1}^n \int_0^\tau \Psi(s) [dN_j(s) - Y_j(s) \times \lambda_0(s) \exp[\hat{\beta}' X_j(s)] ds] \quad (33)$$

converges in distribution to a normal random variable with mean $\mathbf{0}$ and covariance matrix $\Sigma(\tau)$. The expression for $\Sigma(\tau)$ is quite involved so we refer the reader to [23]. The estimator $\hat{\beta}$ is the partial-likelihood maximum-likelihood estimator (PLMLE). Consequently, an asymptotic α -level goodness-of-fit test for $H_0 : \lambda(\cdot) = \lambda_0(\cdot)$ rejects H_0 if

$$S(\tau; \hat{\beta}) \equiv \frac{1}{n} \hat{U}(\tau; \mathbf{0})' \hat{\Sigma}^-(\tau) \hat{U}(\tau; \mathbf{0}) \geq \chi_{k^*, \alpha}^2 \quad (34)$$

where $\hat{\Sigma}^-(\cdot)$ is a generalized inverse of the covariance matrix estimate $\hat{\Sigma}(\cdot)$ and $\chi_{k^*, \alpha}^2$ is the $(1 - \alpha)$ 100th percentile of the χ^2 distribution with degrees of freedom $k^* = \text{rank}[\hat{\Sigma}(\tau)]$ (cf., Li and Doss [27, Theorem 2]).

As mentioned earlier, varying the form of the smoothing process Ψ generates a rich class of tests. In order to come up with closed-form expressions, let us consider the no-covariate setting, that is, we take $X = \mathbf{0}$. Under this framework, three possible consistent estimators of $\Sigma(\tau)$ are

$$\hat{\Sigma}(\tau) = \frac{1}{n} \sum_{j=1}^n \int_0^\tau \Psi(t) \Psi(t)' Y_j(t) \lambda_0(t) dt \quad (35)$$

$$\tilde{\Sigma}(\tau) = \frac{1}{n} \sum_{j=1}^n \int_0^\tau \Psi(t) \Psi(t)' dN_j(t) \quad (36)$$

and

$$\begin{aligned} \hat{\Sigma}(\tau) &= \frac{1}{2n} \sum_{j=1}^n \int_0^\tau \Psi(t) \Psi(t)' \\ &\quad \times [dN_j(t) + Y_j(t) \lambda_0(t) dt] \\ &= \frac{\hat{\Sigma}(\tau) + \tilde{\Sigma}(\tau)}{2} \end{aligned} \quad (37)$$

Monte Carlo simulation studies have shown that using the estimator $\hat{\Sigma}(\tau)$ results in tests with achieved levels that are more consistent with the prespecified levels.

If we let $k = 1$ and $\Psi(t) = 1$, then we obtain the test statistic

$$Q(\tau) \equiv \frac{1}{\sqrt{n}} U(\tau) = \frac{1}{\sqrt{n}} \sum_{j=1}^n [N_j(\tau) - R_{jv_j}^\tau] \quad (38)$$

where $R_{jv_j}^\tau = \Lambda_0(\tau \wedge W_{jv_j})$ and $\Lambda_0(t) = \int_0^t \lambda_0(s) ds$ is the cumulative hazard function corresponding to λ_0 . Using $\hat{\Sigma}(\tau)$ as the estimator of the variance function results in a test with rejection region

$$S(\tau) = \frac{\left[\sum_{j=1}^n (N_j(\tau) - R_{jv_j}^\tau) \right]^2}{\sum_{j=1}^n R_{jv_j}^\tau} \geq \chi_{1; \alpha}^2 \quad (39)$$

This test can be viewed as a generalization of the Pearson-type 1-degree-of-freedom test proposed by Akritas [28].

On the other hand, choosing $\Psi(t) = \exp[-\Lambda_0(t)]$ and using $\hat{\Sigma}(\tau)$ as the variance estimator yields the test statistic

$$S(\tau) \equiv \frac{2 \left\{ \sum_{j=1}^n \left[\sum_{i=1}^{N_j(\tau)} \exp\{-R_{ji}\} - (1 - \exp\{-R_{jv_j}^\tau\}) \right] \right\}^2}{\sum_{j=1}^n (1 - \exp\{-2R_{jv_j}^\tau\})} \quad (40)$$

where $R_{ji} = \Lambda_0(X_{ji})$ are the generalized **residuals**. Hence, H_0 is rejected when $S(\tau) \geq \chi_{1; \alpha}^2$. This test can be regarded as a generalization of Moses' test (cf.,

Hollander and Proschan [29], Gatsonis *et al.* [30], Horowitz and Neumann [31]).

Another possibility is to let the process $\Psi(t)$ be a stochastic process. In particular, by taking $\Psi(t) = B(t)/B(\tau) - 1/2$, where $B(s) = \sum_{i=1}^n \int_0^s Y_i(u) \lambda_0(u) du$, we obtain the test statistic

$$Q(\tau) = \frac{1}{\sqrt{n}} \times \left[\frac{\sum_{j=1}^{N_*(\tau)} \sum_{l=1}^j \left[\sum_{i=1}^n I\{R_{i v_i}^\tau \geq R_{(l)}\} \right]}{\sum_{i=1}^n R_{i v_i}^\tau} - \frac{N_*(\tau)}{2} \right] \quad (41)$$

and the estimated variance function

$$\hat{\Sigma}(\tau) = \frac{1}{12n} \sum_{i=1}^n R_{i v_i}^\tau \quad (42)$$

where $N_*(\tau) = \sum_{i=1}^n N_i(\tau)$ and $R_{(1)}, \dots, R_{(N_*(\tau))}$ are the ordered generalized residuals of the aggregated processes. The test, which rejects H_0 if $S(\tau) \equiv Q^2(\tau)/\hat{\Sigma}(\tau) \geq \chi_{1,\alpha}^2$, results in a generalization of the spacings test of Barlow *et al.* [32].

One can even take the combination of the three previous smoothing processes to get

$$\Psi(t) = \left[1, \exp\{-\Lambda_0(t)\}, \frac{B(t)}{B(\tau)} - \frac{1}{2} \right]' \quad (43)$$

Simulation results revealed that the combined test is sensitive to a wide range of alternatives and thus shows promise as an omnibus test. We refer the reader to Agustin [24] for the details in this setting. In addition, the polynomial form $\Psi(t) = [1, \Lambda_0(t), \dots, \Lambda_0(t)^{k-1}]'$ was examined in Agustin and Peña [22].

Example 6 Consider the well-known dataset presented in Proschan [1, Table 1] which contains the times between failures of the air conditioning system of 13 Boeing jet planes. Following Presnell *et al.* [33], we will take a major overhaul, indicated by

**, as the time of the first perfect repair. In cases where a major overhaul was not performed, we will take the last observed failure time as the time of the first perfect repair. Since all failure times in between will be regarded as minimal repair times, we assume that τ is large enough so we are able to observe all failures until the time of the first perfect repair. Presnell *et al.* [33] tested the minimal repair assumption and found no evidence against it. Suppose we want to test the hypothesis that $H_0 : \lambda(t) = 1/94.34$, that is, the distribution of the times to first failure of the systems is exponential with mean 94.34 hours. The test statistics and corresponding p values for the generalized Moses' test and the generalized spacings test are 6.21 ($p = 0.0127$) and 5.64 ($p = 0.0176$), respectively. Hence, both tests rejected the exponential assumption at the 5% level of significance.

Let us now turn our attention to the composite hypothesis scenario, where interest is on testing whether the baseline hazard rate function belongs to some parametric family. Hence, the hypotheses of interest are $H_0 : \lambda(\cdot) \in \mathcal{C} \equiv \{\lambda_0(\cdot; \xi) : \xi \in \Xi\}$ versus $H_1 : \lambda_0(\cdot) \notin \mathcal{C}$, with the functional form of $\lambda_0(\cdot)$ assumed to be known, except for the value of ξ .

The embedding class for the hazard rate functions in the composite hypothesis case is given by

$$\mathcal{A}_k = \{\lambda_k(\cdot; \theta, \xi, \beta) = \lambda_0(\cdot; \xi) \exp[\theta' \Psi(\cdot; \xi)] : \theta \in \mathfrak{R}^k\} \quad (44)$$

Since setting $\theta = \mathbf{0}$ recovers the hypothesized class $\mathcal{C}$, we can express the original hypotheses as

$$\begin{aligned} H_0^* : (\theta, \xi, \beta) &\in \{\mathbf{0}\} \times \Xi \times \mathcal{B} \quad \text{versus} \\ H_1^* : (\theta, \xi, \beta) &\in \mathfrak{R}^k \setminus \{\mathbf{0}\} \times \Xi \times \mathcal{B} \end{aligned} \quad (45)$$

The relevant score process for θ is therefore

$$\begin{aligned} U(t; \theta, \xi, \beta) &= \sum_{j=1}^n \int_0^t \Psi(s; \xi) \\ &\quad \times [dN_j(s) - Y_j(s) \lambda_0(s; \xi) \\ &\quad \times \exp[\beta' X_j(s)] \exp[\theta' \Psi(s; \xi)] ds] \end{aligned} \quad (46)$$

The challenge in this setting is the need to contend with two nuisance parameters. For the Cox proportional hazards model, it is common to estimate the

vector of regression coefficients by the PLMLE (cf., Keiding *et al.* [34]). The PLMLE of β , denoted by $\hat{\beta}$, is obtained by solving the equation

$$\sum_{j=1}^n \int_0^\tau [X_j(s) - E(s; \beta)] dN_j(s) = \mathbf{0} \quad (47)$$

where

$$S_{(m)}(t; \beta) = \frac{1}{n} \sum_{j=1}^n X_j(t)^{\otimes m} Y_j(t) \exp[\beta' X_j(t)],$$

$$m = 0, 1, 2 \quad (48)$$

$$E(t; \beta) = \frac{S_{(1)}(t; \beta)}{S_{(0)}(t; \beta)} \quad (49)$$

and for a vector $\mathbf{a}$, $\mathbf{a}^{\otimes 0} = 1$, $\mathbf{a}^{\otimes 1} = \mathbf{a}$, and $\mathbf{a}^{\otimes 2} = \mathbf{a}\mathbf{a}'$. The estimator of ξ , denoted by $\hat{\xi} \equiv \hat{\xi}(\hat{\beta})$, is the solution of

$$\begin{aligned} & \sum_{j=1}^n \int_0^\tau \left(\frac{\partial}{\partial \xi} \log \lambda_0(s; \xi) \right) \\ & \times \left[dN_j(s) - Y_j(s) \lambda_0(s; \xi) \exp[\hat{\beta}' X_j(s)] ds \right] \\ & = \mathbf{0} \end{aligned} \quad (50)$$

Assuming that certain regularity conditions hold, Agustin and Peña [23] showed that an asymptotic α -level goodness-of-fit test for $H_0 : \lambda(\cdot) \in \mathcal{C}$ rejects H_0 whenever

$$\frac{1}{n} \hat{U}(\hat{\xi}, \hat{\beta})' \hat{\Gamma}^-(\hat{\xi}, \hat{\beta}) \hat{U}(\hat{\xi}, \hat{\beta}) \geq \chi_{k^*, \alpha}^2 \quad (51)$$

where $\hat{U}(\hat{\xi}, \hat{\beta})$ is the estimated score process, $\hat{\Gamma}^-(\hat{\xi}, \hat{\beta})$ is a generalized inverse of the estimated limiting covariance matrix of $\hat{U}/\sqrt{n}$ under H_0 , and $\chi_{k^*, \alpha}^2$ is the $(1 - \alpha)100$ th percentile of the central χ^2 distribution with $k^* = \text{rank}[\hat{\Gamma}]$ degrees of freedom.

A key element of this family of tests is the process $\Psi(\cdot)$ which characterizes the family of alternatives that a specific test will be able to detect powerfully. We now explore the use of the specification $\Psi(t) = [\Lambda_0(t; \xi), \Lambda_0^2(t; \xi), \dots, \Lambda_0^k(t; \xi)]'$, where $k \in \{1, 2, \dots\}$ is a fixed smoothing order. With this particular choice of Ψ , we obtain tests with relatively simple forms, which turn out to be functions of the model's

generalized residuals. In the simpler case, where the covariates are time independent, the resulting estimated score statistic is

$$Q(\tau) = \frac{1}{\sqrt{n}} \sum_{j=1}^n \left[\sum_{i=1}^{N_j(\tau)} R_{ji}^\ell - \exp\{\hat{\beta}' X_j\} \frac{(R_{jv_j}^\tau)^{\ell+1}}{\ell+1} \right]_{\ell=1, \dots, k} \quad (52)$$

with $R_{ji} = \Lambda_0(W_{ji}; \hat{\xi})$, $(i = 1, \dots, v_j, j = 1, \dots, n)$ and $R_{jv_j}^\tau = \Lambda_0(\tau \wedge W_{jv_j}; \hat{\xi})$. For smoothing order k , an asymptotic α -level test has rejection region

$$S_k \equiv Q'(\tau) \hat{\Gamma}^-(\tau) Q(\tau) \geq \chi_{k^*, \alpha}^2 \quad (53)$$

where k^* is the rank of $\hat{\Gamma}(\tau)$. The components of the estimated covariance matrix are presented in Agustin and Peña [23]. Simulation results show that these tests are powerful omnibus tests.

Example 7 Consider the LHD machines dataset presented in Blischke and Murthy [4, Table 2.7]. LHD machines were used for moving ore and rock in underground mines in Sweden and a vital subsystem of this machine is the hydraulic system. Over a 2-year period, data consisting of time between successive failures of the hydraulic systems of six LHD machines were recorded. For the purpose of this example, we consider all intermediate repairs as minimal repair and the final repair as the first perfect repair. Since the machines are classified as old, medium age, and relatively new, we will use relative age of the machine as a covariate. Owing to the nature of the classification, we need two binary variables, X_1 and X_2 . Old machines are coded as $X_1 = 1$ and $X_2 = 0$; medium age ones as $X_1 = 0$ and $X_2 = 1$, and relatively new ones as $X_1 = 0$ and $X_2 = 0$. We are interested in testing whether an exponential distribution is a plausible model for the time to first failure of the systems. The relevant hypotheses are therefore, $H_0 : \lambda(\cdot) \in \mathcal{C} \equiv \{\lambda_0(\cdot; \xi) = \xi : \xi \in (0, \infty)\}$ versus $H_1 : \lambda(\cdot) \notin \mathcal{C}$. Incorporating the covariates into the model via the Cox proportional hazards model and using the partial likelihood to derive the estimates of β , we obtain $\hat{\beta} = (0.0541, -0.1028)$. Using these estimates in equation (50) results in $\hat{\xi} = 0.0077$. Suppose we use the polynomial specification with smoothing order $k = 4$. Simulation results in Agustin and Peña [23] showed that $k \in \{3, 4\}$ are promising

omnibus tests. The resulting test statistic and its corresponding p value are $S_4 = 9.9291$ and $p = 0.0416$, respectively. Hence, we conclude that the exponential distribution is not an appropriate model for the time to first failure of the hydraulic systems of the LHD machines.

Concluding Remarks

This article focused on inference procedures for the homogeneous and nonhomogeneous Poisson processes as well as a generalized BBS model. In particular, the maximum-likelihood principle was used to obtain estimators of unknown parameters. Other methods of estimation such as the Bayesian approach are certainly applicable and we refer the reader to the book by Rigdon and Basu [13] for details. For a more general class of models that take frailty into account, parametric estimation procedures are proposed in Stocker and Peña [19], while nonparametric estimation issues are tackled in Peña *et al.* [35]. The issue of efficiently determining the smoothing order for the goodness-of-fit problem is still unresolved. Ledwina [36] and Kallenberg and Ledwina [37] used the Schwartz information criterion as a basis for a data-driven smooth goodness-of-fit test. Their tests, however, are formulated using density functions instead of hazard rate functions. Research is still ongoing for a data-driven version of the hazard-based smooth goodness-of-fit tests.

System Reliability: Computational Algebra Methods

Introduction

Monte Carlo and discrete-event simulation use the “experimental” approach to solving complicated modeling problems in reliability and survival analysis. This is typically a fallback approach taken when analytic solutions to a problem do not exist due to mathematical intractability. This chapter outlines the use of computer algebra systems for solving reliability-modeling problems. Computer algebra systems provide exact solutions to these problems, as opposed to the approximate solutions provided by simulation.

There are many choices of base language that could be used in this context. We use the Maple-based APPL (A Probability Programming Language) developed by Glen *et al.* [1] due to our familiarity with the language. Another reasonable choice would have been the MathStatca program developed by Rose and Smith [2].

We begin with a brief introduction to the data structures used in APPL. We then proceed to a series of examples of reliability-modeling problems that can be solved using the language.

Data Structures

One of the initial issues associated with the development of a computer language for solving probability problems concerns how to represent a random variable. APPL uses a “list-of-lists” data structure to represent a random variable, where the first sublist gives the functional form that represents the distribution of the random variable (typically given by a **probability density function**, survivor function, or hazard function), the second sublist gives the support of the random variable, and the third sublist indicates whether the random variable is discrete or continuous and the form of the distribution representation in the first sublist.

As a simple introductory example, consider a continuous random variable X that has a “triangular”

distribution with a minimum of 0, a mode of 1, and a maximum of 3, with probability density function

$$f(x) = \begin{cases} 2x/3 & 0 \leq x < 1 \\ 1 - x/3 & 1 \leq x < 3 \end{cases} \quad (1)$$

This random variable is instantiated in the list-of-lists format with the Maple command

```
> X := [[x -> 2 * x/3, x -> 1 - x/3],  
[0, 1, 3], ["Continuous", "PDF"]];
```

The three integers in the second sublist denote the endpoints of the piecewise support of X . Likewise, a discrete random variable X with probability density function

$$f(x) = \begin{cases} 0.6 & x = 1 \\ 0.3 & x = 2 \\ 0.1 & x = 3 \end{cases} \quad (2)$$

is instantiated with the Maple command

```
> X := [[0.6, 0.3, 0.1], [1, 2, 3],  
["Discrete", "PDF"]];
```

The data structure described above is needed for arbitrarily distributed random variables. Common distributions, such as the binomial and normal distributions, have shortcuts for defining the random variable of interest. The names of the functions for these distributions begin with an uppercase letter and end with an appended RV, for random variable. For example, the APPL command

```
> X := TriangularRV(0, 1, 3);
```

is a shortened and equivalent statement to the earlier instantiation of the distribution of X . Similarly, the statements

```
> Y := BinomialRV(10, 2 / 3);  
> Z := NormalRV(mu, sigma);
```

define a random variable Y having the binomial distribution with parameters $n = 10$ and $p = 2/3$, and a random variable Z having a normal distribution with a symbolic mean parameter μ and symbolic standard deviation parameter σ , respectively.

Once the data structure for defining the distribution of a random variable had been established and common distributions preloaded, algorithms were developed that allowed the manipulation of these random variables. A simple example is to find the expected value of a particular random variable. In order to find the mean, variance, **skewness**, and **kurtosis** of the random variable Y defined above for example, execute the APPL statements

2 System Reliability: Computational Algebra Methods

```
> Mean(Y);
> Variance(Y);
> Skewness(Y);
> Kurtosis(Y);
```

which return the mean, variance, skewness, and kurtosis of the binomial random variable as

$$\frac{20}{3}, \frac{20}{9}, -\frac{\sqrt{5}}{10}, \frac{57}{20}$$

The next section considers a series of examples that use algorithms that have been developed in APPL to manipulate random variables.

Examples

This section contains the following examples of the use of a computer algebra system for reliability analysis: (a) analyzing a k -out-of- n system; (b) finding the mean time to system failure of a parallel system with symbolic parameters; (c) finding a conditional percentile of a system with differing supports for each of its components; (d) finding the distribution of the sum of independent and identically distributed random variables in order to determine the probability of mission success; (e) finding a lower confidence bound for the system reliability; and (f) finding the exact distribution of a goodness-of-fit statistic.

System Survivor Functions

Consider a 4-out-of-5 system that operates when four or five of the components are functioning. Let each component have an independent and identically distributed Weibull time to failure with survivor function

$$S(t) = e^{-(3t)^2}, \quad t > 0 \quad (3)$$

Find

1. the hazard function of the time to system failure;
2. the mean time to system failure;
3. the variance of the time to system failure;
4. the probability that the system survives to time 0.25.

The APPL code to calculate these quantities is

```
X := WeibullRV(3, 2);
Y := OrderStat(X, 5, 2);
HF(Y);
```

```
Mean(Y);
Variance(Y);
SF(Y, 1 / 4);
```

The first statement defines the random variable X , which is associated with the lifetimes of the components. Since this system has five components, and the system failure occurs upon the second failure, the system lifetime is the second-order statistic (see Evans *et al.* [3], for more details) of five independent Weibull random variables, denoted by Y . The HF function returns the hazard function of the system time to failure, which is

$$h(t) = \frac{360t(e^{-9t^2} - 1)}{4e^{-9t^2} - 5}, \quad t > 0 \quad (4)$$

The mean and variance of the system time to failure are

$$E[T] = \frac{5\sqrt{\pi}}{12} - \frac{2\sqrt{5}\pi}{15} \cong 0.2101 \quad \text{and} \\ V[T] = \frac{1}{20} - \frac{21\pi}{80} - \frac{\sqrt{5}\pi}{9} \cong 0.005867 \quad (5)$$

The probability that the system survives to time 0.25 is determined by the SF function, which yields $S(0.25) = 5e^{-9/4} - 4e^{-45/16} \cong 0.2868$.

Symbolic Parameters

Consider an n -component parallel system consisting of components with independent and identically distributed exponential(λ) lifetimes. Find the expected time to system failure.

Since the reliability function of a parallel system of n identical components, each with reliability p , is

$$r(p) = 1 - (1 - p)^n \quad (6)$$

and the survivor function of an exponential random variable with failure rate λ is

$$S(t) = e^{-\lambda t}, \quad t > 0 \quad (7)$$

the system survivor function is

$$S(t) = 1 - (1 - e^{-\lambda t})^n, \quad t > 0 \quad (8)$$

The mean time to system failure is

$$E[T] = \int_0^\infty (1 - (1 - e^{-\lambda t})^n) dt \quad (9)$$

This quantity can be calculated, for instance when $n = 5$, with the APPL statements

```
X := ExponentialRV(lambda);
T := MaximumIID(X, 5);
Mean(T);
```

which return a mean time to system failure of $E[T] = 137/60\lambda$. This problem can also be solved symbolically using the following Maple statements, avoiding the use of APPL entirely:

```
assume(lambda > 0);
n := 5;
s := 1 - (1 - exp(-lambda*t)) ^ n;
int(s, t = 0 .. infinity);
```

which also return a mean time to system failure of $E[T] = 137/60\lambda$. The advantage afforded by APPL is that the mathematical details associated with the derivation can be bypassed.

Lifetimes with Varying Support

Consider the three-component system with component 1 in parallel with the series arrangement of components 2 and 3, i.e., a three-component system with minimal path sets $\{1\}$ and $\{2, 3\}$. Let T_1 , T_2 , and T_3 be the independent lifetimes of the three components, where

$$T_1 \sim U(2, 10), \quad T_2 \sim U(4, 14), \quad T_3 \sim U(6, 18) \quad (10)$$

Find the 95th percentile of the distribution of the failure time of a system that has survived to time 8.

Although this particular problem is conceptually straightforward, keeping track of the various supports is tedious. The APPL code to solve this problem is given below.

```
T1 := UniformRV(2, 10);
T2 := UniformRV(4, 14);
T3 := UniformRV(6, 18);
T := Maximum(T1, Minimum(T2, T3));
TC := Truncate(T, 8, infinity);
CriticalPoint(TC, 0.95);
```

This code returns the 95th percentile of the distribution of the remaining system lifetime as

$$\frac{32 - \sqrt{31}}{2} \cong 13.2161 \quad (11)$$

One way to verify this solution is *via Monte Carlo simulation*, which is also possible in APPL and Maple, although not computationally efficient in either language. The Maple code below generates 10 000 system lifetimes and estimates the quantity of interest. Maple's rand function generates a random 12-digit integer.

```
variates := [];
for i from 1 to 10000 do
    t1 := 2 + 8 * rand()/1000000000000;
    t2 := 4 + 10 * rand()/1000000000000;
    t3 := 6 + 12 * rand()/1000000000000;
    t := max(t1, min(t2, t3));
    if (t > 8) then
        variates := [op(variates), t];
    fi;
od;
variates := sort(variates);
n := nops(variates);
print(evalf(variates[floor(0.95*n)]));
```

The output of several runs of this code segment hovers around the theoretical value, which verifies the analytic solution provided by APPL.

Cold Standby Systems

Let X_1, X_2, X_3 be independent gamma distributed random variables that represent the lifetime of a unit (X_1) and the lifetimes of two backup cold standby units (X_2 and X_3) taken on a mission of duration 50. If $X_1 \sim \text{gamma}(1/2, 3)$, $X_2 \sim \text{gamma}(1/4, 5)$, and $X_3 \sim \text{gamma}(1/6, 7)$, find the probability that the mission is successful.

The two standard ways to address a problem of this type are the central limit theorem and Monte Carlo simulation. Since there are only three random variables being added here, the central limit theorem will not be particularly accurate. Monte Carlo simulation, on the other hand, requires custom programming and the result is typically stated as an interval around the true value. Also, the number of replications required is a quadratic function of the desired accuracy: each additional digit of accuracy to construct such an interval requires a 100-fold increase in the number of Monte Carlo replications.

Alternatively, the APPL code required to solve this problem exactly is

4 System Reliability: Computational Algebra Methods

```
> X := GammaRV(1 / 2, 3);
> Y := GammaRV(1 / 4, 5);
> Z := GammaRV(1 / 6, 7);
> W := Convolution(X, Y);
> T := Convolution(W, Z);
> SF(T, 50);
```

which yields the probability of a successful mission as

$$\frac{246\,009\,667}{256}e^{-25/3} - 61\,758\,360e^{-25/2} + \frac{2199}{256}e^{-25} \cong 0.8371 \quad (12)$$

Bootstrapping

Bootstrapping is a popular statistical technique that involves **resampling** data in order to draw inferences. Bootstrapping involves drawing B “**bootstrap**” samples of n observations without replacement from the n data values collected. Resampling introduces error (because of the finite value of B) that, in some instances, can be eliminated by using APPL. The advice in the literature makes the choice of B nontrivial for a novice to bootstrapping, e.g., “ B in the range of 50 to 200 usually makes $\hat{se}_{boot}$ a good **standard error** estimator, even for estimators like the median” (Efron and Tibshirani [4, p. 14]) or “ B should be ≥ 500 or 1000 in order to make the variability of [the estimated 95th percentile] acceptably low” for estimating 95th **percentiles** (Efron and Tibshirani [4, p. 275]). Because exact values are always preferred to approximations, there is no point to adding the resampling error to the sampling error inherent in the data. In addition, a novice to bootstrapping can easily confuse the **sample size** n with number of bootstrap samples B . Eliminating the resampling of the dataset B times simplifies the conceptualization of the bootstrap process.

Consider the problem of using bootstrapping to determine a 95% lower confidence bound on the system reliability for a series system of three independent components using the failure data (y_i, n_i) , where

Table 1 Failure data for a three-component series system

Component number	$i = 1$	$i = 2$	$i = 3$
Number passing (y_i)	21	27	82
Number on test (n_i)	23	28	84

y_i is the number of components of type i that pass the test and n_i is the number of components of type i on test, $i = 1, 2, 3$ (see Leemis [5]). The number of components tested and the number of passes for each type of component for the example are given in Table 1. The point estimate for the system reliability is

$$\frac{21}{23} \cdot \frac{27}{28} \cdot \frac{82}{84} = \frac{1107}{1288} \cong 0.8595 \quad (13)$$

To calculate an approximate 95% lower bound for the system reliability, the bootstrapping procedure resamples B of the systems, calculates the system reliability, and then returns the 0.05 B th-ordered system reliability. More specifically, for the three-component system of interest, the bootstrapping algorithm follows these steps:

- For the first component, the dataset (21 ones and 2 zeros) is sampled with replacement 23 times.
- These values are summed and divided by 23 yielding a reliability estimate for the first component.
- The previous two steps are repeated for components 2 and 3.
- The product of the reliability estimates for the three components are multiplied (because the components are arranged in series and their failures are independent) to give a system reliability estimate.

The above procedure is repeated B times. The B system reliability estimates are then sorted. Finally, the 0.05 B th-ordered system reliability, a lower 95% bootstrap **confidence interval** bound on the system reliability, is returned.

As in the previous example, a finite choice for B will result in resampling error, which can be avoided by using APPL. The APPL statements given below utilize the `Product` and `Transform` procedures. This alternative approach to determining a lower 95% bootstrap confidence interval bound on the system reliability is equivalent to using an infinite value for B .

```
> X1 := BinomialRV(23, 21 / 23);
> X1 := Transform(X1, [[x -> x / 23],
[-infinity, infinity]]);
> X2 := BinomialRV(28, 27 / 28);
> X2 := Transform(X2, [[x -> x / 28],
[-infinity, infinity]]);
```

```

> X3 := BinomialRV(84, 82 / 84);
> X3 := Transform(X3, [[x -> x / 84],
[-infinity, infinity]]);
> Temp := Product(X1, X2);
> T := Product(Temp, X3);

```

The binomial distribution is appropriate since the resampling from the dataset is performed with replacement. Because the support of X_i contains $n_i + 1$ values, for $i = 1, 2, 3$, there are a possible $24 \cdot 29 \cdot 85 = 59\,160$ potential mass values for the random variable T determined by the `Product` procedure. Of these, only 6633 are distinct because the `Product` procedure combines repeated values. The lower 95% bootstrap confidence interval bound is the 0.05 fractile of the distribution of T , which is $6723/9016 \cong 0.7457$. This value has been verified by Monte Carlo simulation.

Kolmogorov–Smirnov Test Statistic

After fitting a parametric distribution to component or system life data, the model adequacy should be assessed. The Kolmogorov–Smirnov test statistic D_n is used for testing goodness of fit, and is most appropriate when data are sampled randomly from a continuous population. The Kolmogorov–Smirnov test statistic D_n is the largest vertical distance between an empirical cumulative distribution function $F_n(x)$ and a fitted or hypothesized cumulative distribution function $\hat{F}(x)$ for all values of x , i.e.,

$$D_n = \sup_x \{|F_n(x) - \hat{F}(x)|\} \quad (14)$$

The empirical cumulative distribution function $F_n(x)$ is the proportion of the observations $X_1, X_2, \dots, X_n$ that are less than or equal to x and is defined as

$$F_n(x) = \frac{I(x)}{n} \quad (15)$$

where n is the size of the random sample and $I(x)$ is the number of X_i 's less than or equal to x . In other words, $F_n(x)$ is the proportion of the sample that is less than or equal to x .

Unfortunately, the distribution of the test statistic under the null hypothesis is mathematically intractable. An algorithm has been developed to find the distribution of the test statistic in the “all-parameters-known” case (Drew *et al.* [6]). Although computationally intensive for large sample sizes, the

algorithm returns the cumulative distribution function of the Kolmogorov–Smirnov test statistic. This algorithm was implemented in the APPL procedure `KSRV` as illustrated in the example below.

Find the probability density function and the variance of the Kolmogorov–Smirnov test statistic in the all-parameters-known case for a sample of size $n = 3$. The APPL code to solve this problem is

```

> X := KSRV(3);
> Variance(X);

```

which returns the cumulative distribution function as

$$F(x) = \begin{cases} 48x^3 - 24x^2 + 4x - 2/9 & 1/6 \leq x < 1/3 \\ -12x^3 + 14x^2 - 8x/3 & 1/3 \leq x < 1/2 \\ -4x^3 + 2x^2 + 10x/3 - 1 & 1/2 \leq x < 2/3 \\ 2x^3 - 6x^2 + 6x - 1 & 2/3 \leq x < 1 \end{cases} \quad (16)$$

and the variance as exactly $38\,827/2\,099\,520$, or approximately 0.01849. The lower limit of the support of X corresponds to the case of the hypothesized cumulative distribution function bisecting the risers of the empirical cumulative distribution function. The `KSRV` function works for all values of its argument, limited by CPU and memory requirements associated with the algorithm.

Conclusion

There are a variety of problems associated with the calculation of the reliability of a system of components that can be effectively addressed with a computer algebra system. These provide an exact solution to analytically tractable systems analysis problems, providing an alternative to Monte Carlo simulation, discrete-event simulation, and approximate methods.

Genetic Algorithms in Reliability

Introduction

Reliability is an important research area attracting many researchers due to its critical importance in various systems. In fact, reliability plays a vital role in society. People everywhere depend continually on complex technological systems such as washing machines, telephones, televisions, cars, planes, and so on, and every time we use any of these systems, we expect that they perform the task they are intended for. This general idea that something should be fit for purpose is more properly defined as reliability.

For engineering purposes, reliability, $R(t)$, is defined as the probability that a system will perform its intended function during a specified period under stated conditions. Mathematically, this can be expressed as

$$R(t) = \int_t^{\infty} f(x) dx \quad (1)$$

where $f(t)$ is the **probability density function** for the failure time.

In recent years, metaheuristics have been selected and successfully applied to solve several reliability-optimization problems, as described by Gen and Cheng [1]. Genetic algorithms (GAs) are one of the most widely used metaheuristics and they have proved to be powerful tools for effectively solving complex engineering optimization problems.

Genetic Algorithms

GAs, originally developed by Holland [2], are non-deterministic stochastic search/optimization methods that simulate the process of natural evolution to solve problems with a complex solution space. GAs remain the most recognized form of evolutionary computation algorithms. In GA terminology, a solution vector $\mathbf{x} \in \mathbf{X}$ is called an *individual* or a *chromosome*. Chromosomes are made of discrete units called *genes*. Each gene controls one or more features of the chromosome. In the original implementation of GA by Holland [2], genes are assumed to be binary digits.

In later implementations, more varied gene types have been introduced. Normally, a chromosome corresponds to a unique solution $\mathbf{x}$ in the solution space. This requires a mapping mechanism between the solution space and the chromosomes. This mapping is called an *encoding*. In fact, GA works on the *encoding* of a problem, not on the problem itself [3].

In its general form, a GA has an initial population of individuals that is generated either randomly or heuristically. At every generation, the individuals in the current population are decoded and evaluated according to some predefined quality criterion, referred to as the *fitness function*. Creation of new members is done by *crossover* and *mutation* operations. The performance of the algorithm is mainly influenced by these two operators. The primary purpose of the crossover operator is to get genetic material from the previous generation to the subsequent generation, while the main purpose of the mutation operator is to introduce a certain amount of randomness into the search.

The effectiveness of the *crossover* operator dictates the rate of convergence; while the *mutation* operator prevents the algorithm from prematurely converging to a local optimum. In the selection procedure, individuals are chosen according to their fitness value. Individuals with high fitness values have better chances of reproducing, while low-fitness ones are more likely to disappear. The procedure is terminated either when the search process stagnates or when a predefined number of generations is reached.

Since GAs are advanced search mechanisms, they offer the capability of exploring large and complex problem spaces. However, it is important to not forget that GAs are stochastic iterative processes and they are not guaranteed to converge to the global optimal solution. Hence, the termination condition may be specified as some fixed maximum number of generations or as the attainment of an acceptable fitness level. Figure 1 shows the flowchart of a single-objective GA.

A very remarkable point of the GAs is that although they use the idea of randomness when performing a search, it must be clearly understood that GAs are not simply random search algorithms. Random search algorithms can be inherently inefficient due to the directionless nature of the search. The GAs are not directionless. They use knowledge from previous generations of chromosomes (i.e., solution encodings) to construct new chromosomes that will

Figure 1 Single-objective genetic algorithm

approach the optimal solution. Thus, GAs are a form of a randomized search and the way that the parent solutions are chosen and combined comprise a stochastic process; see Lisnianski and Levitin [4]. A comprehensive description of GA theory and its application in engineering can be found in Goldberg [5] and Gen and Chen [1].

Redundancy Allocation Problem

There are many system design engineering projects that require the use of **redundancy** to meet high reliability specifications. To make systems more reliable, redundant units are usually allocated, such that the overall reliability is maximized. However, the use of redundancy also adds more cost, weight, volume, and so on, to the system. There also generally exist system-level constraints and the problem is then to select the design configuration that maximizes some

Figure 2 Series-parallel redundancy system

stated objective functions. This is known as the redundancy allocation problem (RAP). Solving the RAP has been shown to be NP hard by Chern [6] and different mathematical optimization approaches have been used to determine optimal or good solutions to this problem [7–12].

The RAP is a system design optimization problem and probably the most-studied design configuration of the RAP is the series-parallel system, such as depicted in Figure 2. This system has a total of s subsystems arranged in series. For each subsystem, there are n_i functionally equivalent components arranged in parallel. Each component has potentially different levels of cost, weight, reliability, and other characteristics. The n_i components are to be selected from m_i available component types, where multiple copies of each type can be selected. k_i represents the minimum number of components required for subsystem i to function and is specified for each subsystem.

Different problem formulations of the RAP have been presented in the literature. For instance, one well-known example is the following formulation in which the objective is to maximize the system reliability given restrictions on the system cost, C , and the system weight, W :

$$\max \prod_{i=1}^s R_i(\mathbf{x}_i | k_i) \quad (2)$$

subject to:

$$\sum_{i=1}^s C_i(\mathbf{x}_i) \leq C \quad (3)$$

$$\sum_{i=1}^s W_i(\mathbf{x}_i) \leq W \quad (4)$$

$$k_i \leq \sum_{j=1}^{m_i} x_{ij} \leq n_{\max,i} \quad \text{for } i = 1, 2, \dots, s \quad (5)$$

$$x_{ij} \in \{0, 1, 2, \dots\}$$

The problem presented in equations (2–5) is to determine which design alternative to select with the specified level of **component reliability** to achieve the maximum reliability given the overall restrictions on system cost of C and weight of W . In the formulation, x_{ij} is the number of the j th component selection used for subsystem i , and $C_i(\mathbf{x}_i)$ and $W_i(\mathbf{x}_i)$ are the cost and weight for subsystem i .

There are other alternative methods that have been used to solve the RAP. However, metaheuristics seem to be among the preferred techniques. In general, metaheuristics [13–16] can be defined as high-level strategies for exploring search spaces by using different methods. Many researchers have made use of metaheuristics to find solutions for different versions of the RAP [12, 17–20]. However, this article is devoted to the use of GAs in reliability, which is one of the most widely used metaheuristics.

Single-Objective Optimization of Redundant Systems

Solving the RAP as a single-objective optimization problem involves either the maximization of the system design subject to limits on resource consumption or the minimization of the consumption of one resource subject to minimum requirements of system reliability and other resource constraints.

Gen *et al.* [21] and Yokota *et al.* [22] proposed a simple GA to solve reliability-optimization problems. They considered the reliability-optimization problem of a redundancy system with several failure modes originally presented by Tillman [23]. In 1995, Painton and Campbell [24] solved a reliability-optimization problem related to the design of a personal computer. The functional block diagram of the personal computer to be optimized has a series–parallel configuration and a GA was developed to identify the best system configuration by selecting the best combination of components to yield the highest fifth-percentile mean time between failures (MTBF) while remaining within a budget constraint.

In Coit and Smith [25], a GA is presented to analyze series–**parallel systems**, in which each subsystem is **k -out-of- n :G** to determine the **optimal**

design configuration given constraints on reliability, cost, and/or weight, and in [26] they presented a penalty-guided GA to solve the RAP. A different approach was proposed for the solution of the RAP using a combination of neural networks and GAs [27]. Later, Coit and Smith [28] presented a GA to solve the RAP when the objective is to maximize a lower percentile of the system time-to-failure distribution. In 2000, an approach to solve the optimal allocation of a plant design under conflicting safety and economic constraints based on the coupling of **Monte Carlo simulation** and GAs was proposed by Cantoni *et al.* [29].

An extensive overview of some of the methods that have been developed over the last years for solving various system reliability-optimization problems can be found in Kuo and Prasad [30]. A more recent discussion on the use of GAs for the solution of reliability-optimization problems is presented in Marseguerra *et al.* [31].

Genetic Algorithm Operators for Reliability Optimization. An effective GA for RAP depends on problem-specific solution encoding, fitness functions, and complementary crossover and mutation operators. The effectiveness of the crossover operator dictates the rate of convergence, while the mutation operator prevents the algorithm from prematurely converging to a local optimum. The number of children and mutants produced in each generation are tunable parameters that are generally held constant during a specific GA run. There are different possible encodings and operators for RAP; however, those used by Coit and Smith [25] are described in more detail.

Traditionally solution encodings have been a binary string [2]. For combinatorial optimization, an encoding using integer values can potentially be more efficient. For RAP [25], the m_i components are indexed in descending order in accordance with their reliability (i.e., 1 representing the most reliable, etc.). The solution encoding is a vector representation with $s \times n_{\max}$ positions. Each of the s subsystems is represented by $n_{\max}$ positions with the components, which form a particular solution listed according to their reliability index. An index of $m_i + 1$ is assigned to a position where an additional component was not used (i.e., $n_i < n_{\max,i}$). The subsystem representations are then placed adjacent to each other to complete the vector representation.

4 Genetic Algorithms in Reliability

As an example, consider a system with $s = 3$, $m_1 = 5$, $m_2 = 4$, $m_3 = 5$, and $n_{\max,i}$ predetermined to be 5. The following example,

$$\mathbf{v}_1 = (1 \ 1 \ 6 \ 6 \ 6 | 2 \ 2 \ 3 \ 5 \ 5 | 4 \ 6 \ 6 \ 6 \ 6) \quad (6)$$

represents a prospective solution with two of the most reliable components used in parallel for the first subsystem, two of the second most reliable and one of the third most reliable components used in parallel for the second subsystem, and one of the fourth most reliable components used for the third subsystem.

Each solution encoding (called a *genotype*) is associated with a solution to the original problem (called a *phenotype*). For each solution, a *fitness function* is determined. This may be the original objective function adjusted by penalty functions to enforce constraint feasibility.

The crossover breeding operator provides a thorough search of areas of the sample space already demonstrated to produce good solutions. Parents are selected (e.g., roulette wheel, tournament selection) based on their fitness function. There are different types of crossover operators including single-point, double-point, and uniform crossover. As an example [25], uniform crossover retains identical portions of the parents, and then randomly selects, with equal probability, from the two parents for those parts which differ. For example, consider the two following parent vectors ($\mathbf{v}_1$, $\mathbf{v}_2$) and resulting child vector ($\mathbf{v}_c$),

$$\left. \begin{array}{ll} \mathbf{v}_1 = (1 \ 1 \ 6 \ 7 \ 7 \ 3 \ 7 \ 7 \ 7 \ 7) \\ \mathbf{v}_2 = (2 \ 3 \ 6 \ 6 \ 7 \ 2 \ 2 \ 7 \ 7 \ 7) \\ \hline \mathbf{v}_c = (\text{x} \ \text{x} \ 6 \ \text{x} \ 7 \ \text{x} \ \text{x} \ 7 \ 7 \ 7) & - \text{identical indices} \\ \mathbf{v}_c = (2 \ 1 \ 6 \ 7 \ 7 \ 3 \ 2 \ 7 \ 7 \ 7) & - \text{random selection of nonmatching indices} \\ \mathbf{v}_c = (1 \ 2 \ 6 \ 7 \ 7 \ 2 \ 3 \ 7 \ 7 \ 7) & - \text{final arrangement} \end{array} \right\} \quad (7)$$

The mutation operator performs random perturbations to selected solutions. A predetermined number of mutations within a generation is set for each GA trial. Each value within the solution vector (which was randomly selected to be mutated) is changed with probability equal to the mutation rate.

The new solutions can either form a new population, or they can be combined with the previous population and undergo a culling operation. Often elitism is used to retain the solutions with the best fitness functions.

Multiple-Objective Optimization of Redundant Systems

Most actual system engineering optimization problems are multiobjective in nature. This means that these problems have designs with several criteria or design objectives. Most multiple-objective problems (MOPs) have no unique solution that can simultaneously optimize all objectives. Instead, MOPs have a set of potential (nondominated) solutions, the so-called Pareto-optimal set. Existing methods for the solution of MOPs involve either the consolidation of all objectives into a single-objective function, or the determination of a Pareto-optimal set.

Busacca *et al.* [32] proposed a multiobjective GA approach that was applied to a design problem with the aim to identify the optimal system configuration and components with respect to reliability and cost objectives. In 2006, Tian and Zuo [33] applied physical programming to a RAP for multistate systems. They sought to maximize system performance utility while minimizing system cost and system weight simultaneously. In their approach, the multiple objectives considered are aggregated into a single-objective function and a GA is used to solve the proposed physical programming optimization model.

In Taboada and Coit [34] and Taboada *et al.* [35], the RAP was formulated as a multiobjective problem with the system reliability to be maximized, and cost and weight of the system to be minimized as shown

in equations (8 and 9). The Pareto-optimal set was initially obtained using the fast elitist nondominated sorting genetic algorithm (NSGA)-II [36]. Then, the decision-making stage was performed with the aid of two pruning methods to reduce the size of the Pareto-optimal set and obtain a smaller representation of the multiobjective design space.

$$\max \left[\prod_{i=1}^s R_i(\mathbf{x}_i) \right], \min \left[\sum_{i=1}^s \sum_{j=1}^{m_i} c_{ij} x_{ij} \right],$$

$$\min \left[\sum_{i=1}^s \sum_{j=1}^{m_i} w_{ij} x_{ij} \right] \quad (8)$$

Subject to

$$1 \leq \sum_{j=1}^{m_i} x_{ij} \leq n_{\max,i} \quad \text{for } i = 1, 2, \dots, s \quad (9)$$

$$x_{ij} \in \{0, 1, 2, \dots\}$$

Multistate Optimization of Redundant Systems

As we earlier discussed, reliability is defined as the probability that a device is able to perform its intended functions satisfactorily under specified conditions for a specified period. However, traditional reliability assumes that a system and its components can only be in either a working or a failed state. This condition has facilitated the development of a robust and extensive theory to analyze system performance. However, in some cases traditional reliability theory fails to represent the true model of the system. Failure to acknowledge this situation can represent a major deficiency since systems can have a range of intermediate states that are not accounted for in the reliability estimation.

To describe the satisfactory performance of a device, it may be necessary to use more than two levels of satisfaction, e.g., excellent, average, and poor. Multistate reliability has been proposed as a complementary theory to cope with the problem of analyzing systems where traditional reliability theory and models become insufficient. Then, in a multistate system, both the system and its components are allowed to experience more than two possible states, e.g., completely working, partially working or partially failed, and completely failed.

The universal moment generating function (UMGF) can be used to determine the availability of a redundant multistate system, as in Ushakov [37, 38]. In 1998, Levitin *et al.* [39] used a GA for solving the multistate RAP, where the system and its components have a range of performance levels. **System availability** is represented by a multistate availability function, which extends the binary state availability. They evaluated the multistate system availability based on the UMGF. Later, Levitin *et al.* [40] addressed the multistage expansion

problem for multistate series-parallel systems. In this problem, the system-study period is divided into several stages. A more comprehensive explanation completely devoted to multistate system reliability analysis and optimization can be found in Lisnianski and Levitin [4].

Summary and Other Important Related Topics

We have presented an overview of some of the most relevant research that has been done on the use of GAs in **reliability optimization** of redundant systems. As we have described, GAs are powerful tools for effectively solving reliability-optimization problems. However, there are many other applications of GAs in reliability-related problems that were not addressed in this article and are worthy of comment, such as the use of GAs on reliability optimization with alternative design, reliability optimization with time-dependent reliability, reliability optimization with interval coefficients, bicriteria reliability optimization, and reliability optimization with fuzzy goals and fuzzy constraints. For those who are more interested on the topic, reference [41] presents a state-of-the-art survey that covers several GA-based approaches for various reliability-optimization problems.

Reliability, Safety, and Risk Management

Safety and Reliability

A close association between safety and reliability has existed since the earliest times, Cox and Tait [1]. Throughout the history of engineering, reliability improvement, arising as a direct consequence of the analysis of failure, has been a central feature in the development of safe systems (Smith [2]). Until the advent of modern scientific theories, technical progress was made by a sophisticated process of “test and correct”. Engineers and designers learned not only by their own mistakes but also from other people’s misfortunes. This process was quite successful and a significant progress was made, as evidenced by the construction of twelfth- and thirteenth-century buildings throughout Europe and the rest of the developed world. However, the relationship between safety and reliability was intensified as industrial processes proliferated. During the Industrial Revolution (Hobsbawm [3], Ashton [4]) new sources of power, using water or steam, not only gave great opportunities for the rapid development of manufacturing technology, but also presented safety challenges.

At this time scientific developments were strongly deterministic. The approach to safety and reliability during this time was along similar deterministic lines. Structures were designed to a predetermined “load factor” or *factor of safety*, this being the ratio of the load predicted to cause collapse of the structure to the normal operating load. The factor was made large enough to ensure that the structure operated safely even if significant corrosion was present. Fixing the magnitude of the load factor was a relatively arbitrary process, and led at times to considerable argument among practitioners.

Toward the end of the nineteenth century, science had begun to make use of statistical and probabilistic techniques (for example, in gas kinetics). This probabilistic approach entered the safety and reliability field on a large scale as attempts were made to operate electronic and other delicate equipment under battle conditions during the Second World War. Application of the well-tried factor of safety was no longer able to provide a solution, and under the harsh operating

conditions encountered on board ship or in combat aircraft, reliability (or rather, unreliability) became a major problem. Typical airborne radar, for instance, would do well to operate continuously for 1 hour without failure (Wickens [5]). In these circumstances it was necessary to study the causes and effects of component breakdown in order to improve reliability.

At the same time it could be argued that the improvements in **component reliability** and developments in economic prosperity have lead many practitioners to consider a sociotechnical systems approach and include the “human” factor in the process of safety improvement (see Figure 1). The most obvious impetus for this interest has been a growing public concern over the great costs of human error: the Tenerife air disaster in 1977, Three Mile Island 2 years later, Bhopal in 1984 with its considerable loss of lives, and Chernobyl in 1986 with its implications for the public image of the nuclear-power-generating industry worldwide.

An additional spur to the developments in our understanding of human error has come from theoretical and methodological developments in cognitive psychology. It has become increasingly apparent that to provide an adequate picture of control processes psychologists must explain not only correct performance, but also more predictable varieties of human error.

The Human Factor

The study of human factors in systems reliability, through the application of psychology, ergonomics, and human factors engineering, has grown considerably over recent decades. Early researchers in this area complained of the seeming lack of interest in human error by their fellow psychologists, *crammed as psychological writings are, and most needs to be, with allusions to errors in an incidental manner, they hardly ever arrive at considering these profoundly, or even systematically*, Spearman [7].

Human factors have been implicated in the etiology of many accidents within high-reliability organizations. The work of human factors engineers and ergonomists has developed a greater understanding of human task performance and the interactions between humans and complex systems. The type and degree of human participation, especially in “high” consequence areas, has been a matter of increasing concern.

A direct manifestation of the current link between safety and reliability is illustrated through the safety regulation and the requirements for submission of safety case (for further details see www.hse.gov.uk).

The Systems Approach

The systems approach to safety management is based on the applications of general systems theory; the approach adopted by the author integrates engineering, management procedures, and human factors. The approach provides a framework for analyzing, modeling, and managing work and work functions. There are three important characteristics of “systems” that can be applied to a simple safety systems model. First, the components are connected in an organized way and changes in one component affect the others. Second, the behavior of the system changes if any one component is excluded from the system. Third, the organized assembly of components performs some function. Safety systems also have an adaptive response to their wider environments. Figure 2 outlines an objective setting model of the safety of system X.

Risk Management

Risk management is a technique utilized by organizations and public bodies to increase safety and

reliability, and minimize losses. The process involves the identification, evaluation, and control of risks. Risk identification can be achieved using a number of techniques.

Risk evaluation encompasses the measurement and assessment of risk. Implicit in the process is the need for sound decision making on the nature of potential sociotechnical systems and their predicted reliability. Decisions on the acceptability of risk are dependent on a number of factors, which include social, economic, political, and legislative concerns.

The final stage in the management of risk is risk control. Risk control strategies can be classified into four categories: risk avoidance, retention, transfer, and reduction. Risk avoidance involves a conscious decision on the part of the organization to avoid a particular risk by discontinuing the operation that is producing the risk. Risk retention may occur with knowledge (a deliberate decision to retain the risk by, for example, self financing) or without knowledge (occurs when risks have not been identified). Risk transfer is a conscious transfer of risk, i.e., to another organization *via* insurance. Finally risk reduction is the management of systems to reduce risks. A number of techniques, concepts, and strategies in relation to technology, management systems, and human factors are described in the following section.

Analysis Techniques and the Control of the System

Human Reliability Techniques

Human reliability should be an important consideration at all stages of systems design and its later implementation and management. Human reliability can be enhanced by appropriate selection, training, and continuing development of all personnel. Additional enhancement may be obtained from heightened awareness, in appropriate staff, of the design features of plant and equipment that may lead to operational or maintenance errors. Attempts to quantify human reliability have been incorporated into systems thinking since the 1950s – although the majority of the work has taken place in high-reliability organizations, it has been related to the probabilities of human error for critical functions and particularly in emergency situations (Humphreys [8]). The most common measure of human reliability is the human error probability

Figure 2 An objective setting model of the safety of system X [© Elsevier, 1998.]

(HEP), which is the probability of an error occurring during a specified task. HEP is estimated from the ratio of errors committed to the total number of opportunities for error as follows:

$$HEP = \frac{\text{Number of human errors}}{\text{Total number of opportunities for error}} \quad (1)$$

The successful performance probability of a task (or the task reliability) can generally be expressed by $1 - HEP$. Table 1 lists the common human reliability assessment techniques.

The majority of human reliability assessment techniques are based in part on behavioral psychology. They have been derived from empirical models using statistical inference (but are not

always adequately validated) and are dependent on expert judgments, which can be subject to **bias**. One of the most commonly used human reliability assessment techniques is the technique for human error rate prediction (Swain and Guttman [9]); the technique can be broken down into five distinct phases:

1. a systems description, including goal definition and functions;
2. a job and task analysis by personnel to identify likely error situations;
3. an estimation of the likelihood of each potential error as well as of it being undetected (taking account of the performance-shaping factors);
4. an estimate of the consequences of any undetected error; and

Hazard Analysis Techniques

The process of hazard analysis is an overarching technique that allows the systems designer and operators to ensure compliance with safety regulations. Hazard analysis will help analysts understand the hazards resulting from failure better and requires an understanding of the physical and sometimes the chemical properties of the materials involved. Moreover, hazard analysis requires an understanding of the drivers of human behaviors. An important example of the bottom-up approach is the failure modes and effects analysis (FMEA). This method is of particular use when examining the performance of relatively simple components, for determining which types of failure are of danger and which are of safety, and finally for calculating overall failure rates to the two states for the complete component.
